Chapter 1. Overview

1.1. What is Xtext?

Xtext is a framework for the development of [domain-specific languages](#). It is tightly integrated with the [Eclipse Modeling Framework \(EMF\)](#) and leverages the Eclipse Platform in order to provide a language-specific integrated development environment (IDE).

In contrast to common parser generators (like e.g. JavaCC or ANTLR), the Xtext derives much more than just a parser and lexical analyzer (lexer) from an input grammar. The grammar language is used to describe and generate:

- an incremental, ANTLR 3 based parser and lexer to read your models from text,
- Ecore-based meta models (optional)
- a serializer to write your models back to text,
- a linker, to establish cross links between model elements,
- an implementation of the EMF Resource interface (based on the parser and the serializer) and
- a full-fledged integration of the language into the Eclipse IDE.

Some of the IDE features, that are either derived from the grammar or easily implementable, are

- syntax coloring,
- model navigation (F3, etc.),
- code completion,
- outline views and
- code templates.

The generated artifacts are wired up through [Google Guice](#), a dependency injection framework which makes it easy to exchange certain functionality in a non-invasive manner. For example if you do not like the default code assistant implementation, all you need to do is to come up with an alternative implementation of the corresponding service and configure it via [dependency injection](#).

1.2. What is a domain-specific language (DSL)

A DSL is a small programming language, which focuses on a particular domain. Such a domain can be more or less anything. The idea is that its concepts and notation is as close as possible to what you have in mind when you think about a solution in that domain. Of course we are talking about problems which can be solved or processed by computers somehow.

The opposite of a DSL is a so called GPL, a General Purpose Language such as Java or any other common programming language. With a GPL you can solve every computer problem, but it might not always be the best way to solve it.

Imagine you want to remove the core from an apple. You could of course use a swiss army knife to cut it out, and this is reasonable if you have to do it just once or twice. But if you need to do that on a regular basis it might be more efficient to use an apple corer.

There are a couple of well-known examples of DSLs. For instance SQL is actually a DSL which focuses on querying relational databases. Other DSLs are regular expressions or even languages provided by tools like MathLab. Also most XML languages are actually domain-specific languages. The whole purpose of XML is to allow for easy creation of new languages. Unfortunately with XML you are not able to change the concrete syntax, which is the major problem with it. The concrete syntax of XML is way too verbose. Also a generic syntax for everything is a compromise.

Xtext is a sophisticated framework that helps to implement your very own DSL with appropriate IDE support. There is no such limitation as with XML, you are free to define your concrete syntax as you like. It may be as concise and suggestive as possible being a best match for your particular domain. The hard task of reading your model, working with it and writing it back to your syntax is greatly simplified by Xtext.

1.3. Getting Started

In this mini-tutorial you will implement your first language with Xtext and create an editor from that. [Download and install the latest version of Xtext](#), set up a fresh workspace, take a deep breath and follow the instructions.

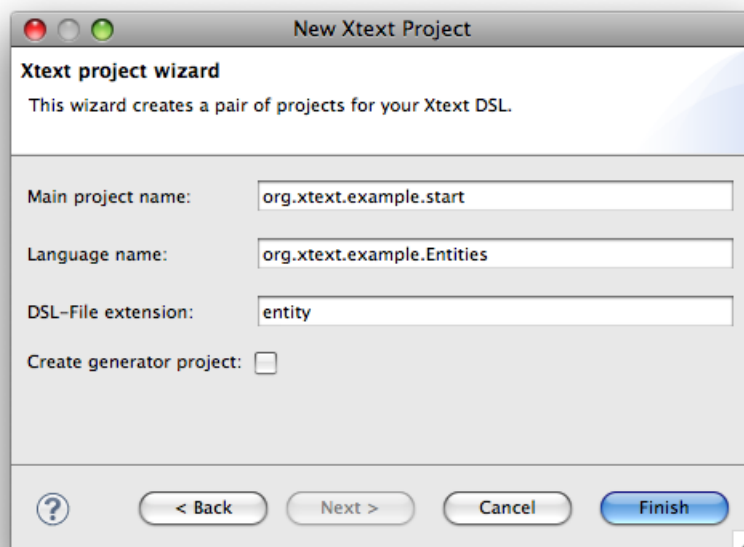

1.3.1. Create an Xtext project

Use the Xtext wizard to create a new project

File # New # Project # Xtext # Xtext project

Choose a sensible project name, language name and file extension, e.g.

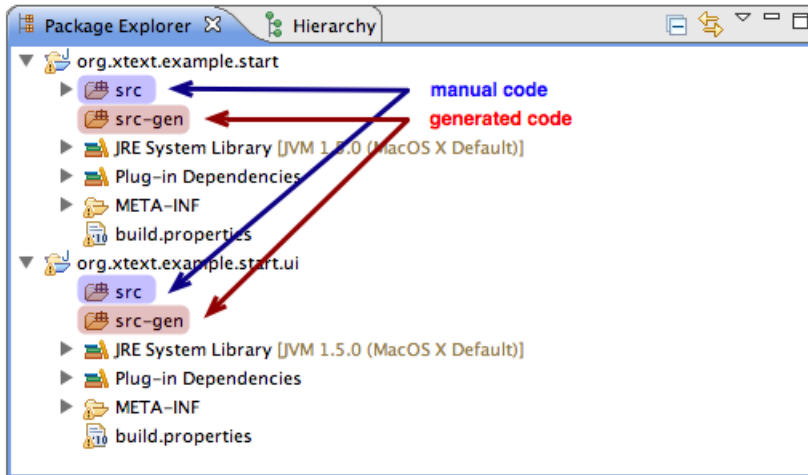

Main project name:	org.xtext.example.start
Language name:	org.xtext.example.Entities
DSL-File extension:	entity

Uncheck “Generate Generator project”, you will not need it this time. Click on Finish.

1.3.2. Project layout

In the Package Explorer you can see two new projects. In `org.xtext.example.start` you can define the grammar and configure the runtime aspects of your language. The editor, outline view and code completion goes into `org.xtext.example.start.ui`. Both projects consist of generated classes derived from your grammar and manual code such as the grammar itself or further classes to differentiate from the default behavior.

It is good to be clear and unambiguous whether the code is generated or is to be manipulated by the developer. Thus, the generated code should be separated from the manual code. We follow this pattern by giving a folder `src/` and a folder `src-gen/` in each project. Keep in mind not to make changes in the `src-gen/` folder. They would be overwritten in the next generation process.

1.3.3. Build you own grammar

If everything went well, the example grammar file `Entities.xtext` from the first project is opened with the Xtext Editor. This grammar has two purposes. First, it describes the concrete syntax of text files that can be processed by the tools of your new language. Second, it equates the meta level, i.e. the model which describes your model.

Ignore the generated sample grammar, delete everything from `"Model :"` to the end. The entry rule for the parser will be called `Model`. As a `Model` consists of one or more `Entity` entries, this rule delegates to another rule named `Entity`, which will be defined later on. As we can have one or more entities within a model, the cardinality is `"+"`. Each rule is terminated with a semicolon. So our first rule reads as

```
Model :
  Entity+;
```

Please note: If you encounter strange errors while copying and pasting these snippets to your Eclipse editor your documentation viewer most likely has inserted characters different from `{space}` into your clipboard. Reenter these “fillers” or type the text by hand to be sure everything works fine.

An Xtext grammar does not only describe rules for the parser but also the structure of the resulting abstract syntax tree. Usually, each parser rule will create a new node in that tree. The type of that node can be specified after the rule name using the keyword `returns`. If the type’s name is the same as the rule name, it can be omitted as in our case.

The parser will create a new element of type `Model` when it enters the rule `Model`, and a new element of type `Entity` every time it enters the rule `Entity`. To connect these AST elements, we have to define the name of a reference. In our case, we call that reference `entities`. We specify it using the assignment operator `"+="`, which denotes a multi valued feature.

As a result, we modify the first rule to

```
Model :
  (entities += Entity)+;
```

The next rule on our list is the rule `Entity`. Looking at our target syntax, each entity begins with the keyword `entity` followed by the entity’s name and an opening curly brace (we will handle the extends clause in a second step). Then, an entity defines a number of properties and ends with a closing curly brace.

```
Entity returns Entity:
  'entity' name=ID '{'
    (properties+=Property)*
  '}';
```

Instead of creating a new AST node for the name, we rather want the name to be an attribute of the `Entity` class. Therefore we use the terminal rule `ID`, which results in a string. The assignment operator “=” denotes a single valued feature, and the asterisk a cardinality of 0..n. In our target syntax, some entities refer to an existing entity as their super type after the keyword `extends`. Note that this is a cross-reference, as the super type itself must be defined somewhere else. To define a cross-reference we use square brackets. Optional parts have the cardinality “?”. The complete rule now reads as

```
Entity returns Entity:
'entity' name=ID ('extends' superType=[Entity])? '{'
(properties+=Property)*
'}';
```

We have not specified the rule `Property`, yet. In our target syntax, properties come in two flavors: `SimpleProperties` starting with the keyword `property` and `AssociationProperties` using the `associates` keyword. As they are referring to different artifacts, we should make separate rules for them. Our rule `Property` will just delegate to either of them, using the “|” separator:

```
Property:
SimpleProperty | AssociationProperty;
```

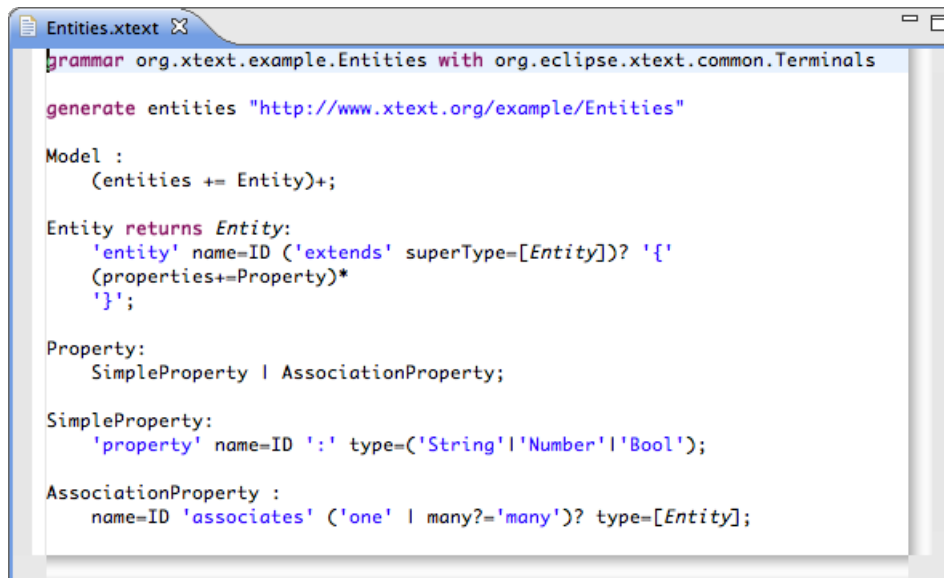

A `SimpleProperty` consists of a keyword, a name, a colon, and a type. The type will be one of `String`, `Number`, or `Bool`. That results in the following parser rule:

```
SimpleProperty:
'property' name=ID ':' type=('String' | 'Number' | 'Bool');
```

An `AssociationProperty` consists of a name, several keywords, and a cross-reference to another `Entity`. The multiplicity is either many or one. The presence of the keyword `many` should trigger a boolean flag in the AST model. This is the purpose of the assignment operator “?=". Our last parser rule is:

```
AssociationProperty :
name=ID 'associates' ('one' | many?='many')? type=[Entity];
```

In the end your grammar editor should look like this:

1.3.4. Generate language artifacts

Save the grammar and make sure that no error markers appear. Then, locate the file `GenerateEntities.mwe` next to the grammar file in the package explorer view. From its context menu, choose

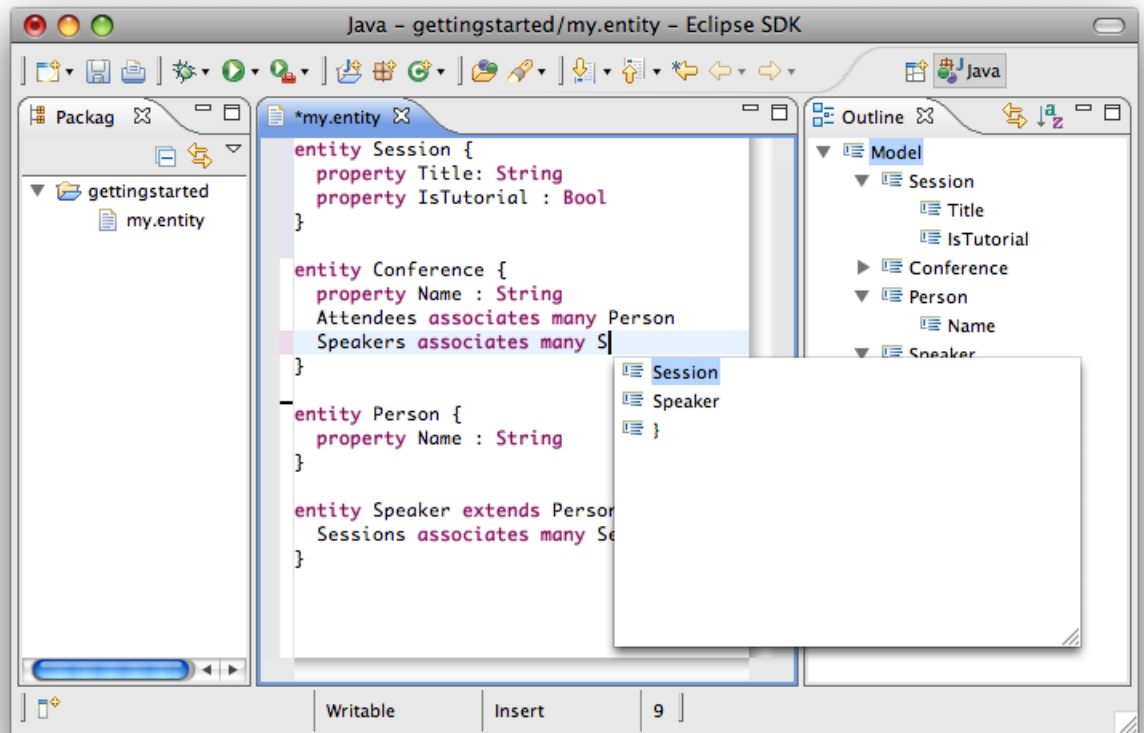

Run As # MWE Workflow.

That will trigger the Xtext language generator. You will see its logging messages in the Console view.

1.3.5. Test the generated editor

If code generation succeeded, right-click on the Xtext project and choose Run As # Eclipse Application.

This will spawn a new Eclipse workbench with your projects as plug-ins installed. In the new workbench, create a new project (File # New # Project # General # Project) and in there a new file with the file extension you chose in the beginning. This will open the generated entity editor. Now play a bit with its features, like outline, content assist, syntax coloring, navigation etc.

Chapter 2. The Grammar Language

The [grammar language](#) is the corner stone of Xtext and is defined in itself. Actually it is a DSL to create DSLs, so what would be more helpful as to develop the Xtext language with Xtext?

The grammar language is a domain specific language, carefully designed for the description of textual languages based on [LL\(*\)-Parsing](#) that is like [Antlr3's parsing strategy](#). The main idea is to describe the concrete syntax and how an EMF-based in-memory model is created during parsing.

2.1. First an example

To get an idea of how it works we'll start by implementing a [simple example](#) introduced by Martin Fowler. It's mainly about describing state machines used as the (un)lock mechanism of secret compartments. People who have secret compartments control their access in a very old-school way, e.g. by opening the door first and turning on the light afterwards. Then the secret compartment, for instance a panel, opens up. One of those state machines could look like this:

```
events
  doorClosed  D1CL
  drawOpened  D2OP
  lightOn     L1ON
  doorOpened  D1OP
  panelClosed PNCL
end

resetEvents
  doorOpened
end

commands
  unlockPanel PNUL
  lockPanel   PNLK
  lockDoor    D1LK
  unlockDoor  D1UL
end

state idle
  actions {unlockDoor lockPanel}
  doorClosed => active
end

state active
  drawOpened => waitingForLight
  lightOn    => waitingForDraw
end

state waitingForLight
  lightOn => unlockedPanel
end

state waitingForDraw
  drawOpened => unlockedPanel
end

state unlockedPanel
  actions {unlockPanel lockDoor}
  panelClosed => idle
end
```

So, we have a bunch of declared events, commands and states. Within states there are references to declared actions, which should be executed when entering such a state. Also there are transitions consisting of a reference to an event and a state. Please read [Martin's description](#) if it is not clear enough.

In order to get a complete IDE for this little language from Xtext, you need to write the following grammar:

```
grammar my.pack.SecretCompartments
  with org.eclipse.xtext.common.Terminals
  generate secretcompartment "http://www.eclipse.org/secretcompartment"

  Statemachine :
    'events'
      (events+=Event)+
    'end'
    ('resetEvents'
      (resetEvents+=[Event])+
    'end')?
    'commands'
      (commands+=Command)+
    'end'
    (states+=State)+;

  Event :
    name=ID code=ID;

  Command :
    name=ID code=ID;

  State :
    'state' name=ID
      ('actions' '{' (actions+=[Command])+ '}' )?
      (transitions+=Transition)*
    'end';

  Transition :
    event=[Event] '=>' state=[State];
```

2.2. The Syntax

In the following the different concepts of the grammar language are explained.

2.2.1. Language Declaration

The first line

```
grammar my.pack.SecretCompartments with org.eclipse.xtext.common.Terminals
```

declares the name of the grammar. Xtext leverages Java's classpath mechanism. This means that the name can be any valid Java qualifier. The file name needs to correspond to the grammar name and have the file extension 'xtext'. This means that the name needs to be `SecretCompartments.xtext` and must be placed in package `my.pack` somewhere on your project's class path.

The first line is also used to declare any used language (for mechanism details cf. [Grammar Mixins](#)).

2.2.2. EPackage declarations

Xtext parsers instantiate Ecore models (aka meta model). An Ecore model basically consists of an EPackage containing EClasses, EDatatypes and EEnums. Xtext can infer Ecore models from a grammar (see [Meta-Model Inference](#)) but it is also possible to instantiate existing Ecore models. You can even mix this and use multiple existing Ecore models and infer some others from one grammar.

2.2.2.1. EPackage generation

The easiest way to get started is to let Xtext infer the meta model from your grammar. This is what is done in the secret compartment example. To do so just state:

```
generate secretcompartment http://www.eclipse.org/secretcompartment
```

That means: generate an EPackage with name `secretcompartment` and nsURI `http://www.eclipse.org/secretcompartment` (these are the properties needed to create an

EPackage). The whole algorithm used to derive complete Ecore models from Xtext grammars is described in section [Meta-Model Inference](#).

2.2.2.2. EPackage import

If you already have an existing EPackage, you can import it using either a namespace URI or a resource URI (URIs are an EMF concept).

Using namespace URIs to import existing EPackages

You can import an existing EPackage with the following statement:

```
import "http://www.eclipse.org/secretcompartment"
```

Note that if you use a namespace URI, the corresponding EPackage needs to be installed into the workbench, so that the editor can find it. At runtime (i.e. when starting the generator) you need to make sure that the corresponding EPackage is registered in the `EPackage.Registry.INSTANCE`. If you use MWE to drive your code generator, you need to add the following lines to your workflow file:

```
<bean class="org.eclipse.emf.mwe.utils.StandaloneSetup"
  platformUri="{runtimeProject}/..">
  <registerGeneratedEPackage value="my.pack.SecretcompartmentPackage"/>
</bean>
```

using namespace URIs is typically only interesting when common Ecore models are used, such as Ecore itself or the UML metamodel. If you're developing the EPackage together with the DSL but don't want to have it derived from the grammar for some reason, we suggest to use a resource URI.

Using resource URIs to import existing EPackages

If the EPackage you want to use is somewhere in your workspace you should refer to it by a `platform:/resource/-URI`. Platform URIs are a special EMF concept, which allow for some kind of transparency between workspace projects and installed bundles. Consult the EMF documentation (we recommend the book) for details.

An import statement referring to an Ecore file by a `platform:/resource/` URI looks like this:

```
import "platform:/resource/project/src/my/pack/SecretCompartments.ecore"
```

If you want to mix generated and imported Ecore models you'll have to configure the generator fragment in your MWE file responsible for generating the Ecore classes ([EcoreGeneratorFragment](#)) with resource URIs that point to the genmodels for the referenced Ecore models. Example:

```
<fragment class="org.eclipse.xtext.generator.ecore.EcoreGeneratorFragment"
  genModels=
    "platform:/resource/project/src/my/pack/SecretCompartments.ecore"/>
```

2.2.2.3. Meta model aliases for packages

If you want to use multiple EPackages you need to specify aliases in the following way:

```
generate secretcompartment 'http://www.eclipse.org/secretcompartment'
import 'http://www.eclipse.org/anotherPackage' as another
```

When referring to a type somewhere in the grammar you need to qualify the reference using that alias (example `another::CoolType`). We'll see later where such type references occur.

It is also supported to put multiple EPackage imports into one alias. This is no problem as long as there are not any two EClassifiers with the same name. In such cases none of them can be referenced. It is even possible to have multiple "import"s and one "generate" declared for the same alias. If you do so, for a reference to an EClassifier first the imported EPackages are scanned before it is assumed that a type needs to be generated into the to-be-generated package.

Example:

```
generate toBeGenerated 'http://www.eclipse.org/toBeGenerated'
import 'http://www.eclipse.org/packContainingClassA'
import 'http://www.eclipse.org/packContainingClassB'
```

With the declaration above

1. a reference to type `ClassA` would be linked to the `EClass` contained in `http://www.eclipse.org/packContainingClassA`,
2. a reference to type `ClassB` would be linked to the `EClass` contained in `http://www.eclipse.org/packContainingClassB`,
3. a reference to type `NotYetDefined` would be linked to a newly created `EClass` in `http://www.eclipse.org/toBeGenerated`.

Note, that using this feature is not recommended, because it might cause problems, which are hard to track down. For instance, a reference to `"classA"` would as well be linked to a newly created `EClass`, because the corresponding type in `http://www.eclipse.org/packContainingClassA` is spelled with a capital letter.

2.2.3. Rules

The default parsing is based on a homegrown packrat parser. It is advise to substitute it by an ANTLR parser through the Xtext service mechanism. ANTLR is a sophisticated parser generator framework based on an LL(*) [parsing algorithm](#), that works quite well for Xtext. Please download the plugin `de.itemis.xtextantlr` (from update site `http://download.itemis.com/updates/`) and use the ANTLR Parser instead of the packrat parser (cf. [Xtext Workspace Setup](#)).

Basically parsing can be separated in the following phases.

1. lexing
2. parsing
3. linking
4. validation

2.2.3.1. Terminal Rules

In the first stage, i.e. lexing, a sequence of characters (the text input) is transformed into a sequence of so called tokens. A token is sort of a strongly typed part of the input sequence. It consists of one or more characters and was matched by a particular terminal rule and represents an atomic symbol. In the secret compartments example there are no explicitly defined terminal rules, since it only uses the `ID` rule which is inherited from the grammar `org.eclipse.xtext.common.Terminals` (cf. [Grammar Mixins](#)). Terminal rules are also referred to as token rules or lexer rules. There is an informal naming convention that terminal-rule names are all upper-case.

Therein the `ID` rule is defined as follows:

```
terminal ID :
    ('^')? ('a'..'z' | 'A'..'Z' | '_' ) ('a'..'z' | 'A'..'Z' | '_' | '0'..'9')* ;
```

It says that a Token `ID` starts with an optional `^` character, which is called caret, followed by a letter (`'a'..'z' | 'A'..'Z'`) or underscore (`'_'`) followed by any number of letters, underscores and numbers (`'0'..'9'`).

The caret is used to escape an identifier for cases where there are conflicts with keywords. It is removed by the `ID` rule's [ValueConverter](#).

This is the formal definition of terminal rules:

```
TerminalRule :
    'terminal' name=ID ('returns' type=TypeRef)? ':'
        alternatives=TerminalAlternatives ';'
    ;
```

Note, that the order of terminal rules is crucial for your grammar, as they may hide each other. This is especially important for newly introduced rules in connection with mixed rules from used grammars.

If you for instance want to add a rule to allow fully qualified names in addition to simple IDs, you should implement it as a [datatype rule](#), instead of adding another terminal rule.

Return types

A terminal rule returns a value, which is a string (type `ecore::EString`) by default. However, if you want to have a different type you can specify it. For instance, the rule ‘INT’ is defined as:

```
terminal INT returns ecore::EInt :
    ('0'..'9')+;
```

This means that the terminal rule INT returns instances of `ecore::EInt`. It is possible to define any kind of data type here, which just needs to be an instance of `ecore::EDDataType`. In order to tell the parser how to convert the parsed string to a value of the declared data type, you need to provide your own implementation of ‘`IValueConverterService`’ (cf. [value converters](#)).

The implementation needs to be registered as a service (cf. [Service Framework](#)).

This is also the point where you can remove things like quotes from string literals or the caret (‘^’) from identifiers.

2.2.3.2. Extended Backus-Naur form expressions

Token rules are described using “Extended Backus-Naur Form”-like (EBNF) expressions. The different expressions are described in the following. The one thing all of these expressions have in common is the quantifier operator. There are four different quantities

1. exactly one (the default no operator)
2. one or none (operator “?”)
3. any (operator “*”))
4. one or more (operator “+”)

Keywords / Characters

Keywords are a kind of token rule literals. The ID rule in `org.eclipse.xtext.common.Terminals` for instance starts with a keyword :

```
terminal ID : '^'? .... ;
```

The question mark sets the cardinality to “none or one” (i.e. optional) like explained above.

Note that a keyword can have any length and contain arbitrary characters.

Character Ranges

A character range can be declared using the ‘..’ operator.

Example:

```
terminal INT returns ecore::EInt: ('0'..'9')+ ;
```

In this case an INT is comprised of one or more (note the ‘+’ operator) characters between (and including) ‘0’ and ‘9’.

Wildcard

If you want to allow any character you can simply write the wildcard operator ‘.’ (dot): Example:

```
FOO : 'f' . 'o' ;
```

The rule above would allow expressions like ‘foo’, ‘f0o’ or even ‘f\no’.

Until Token

With the until token it is possible to state that everything should be consumed until a certain token occurs. The multiline comment is implemented this way:

```
terminal ML_COMMENT : '/*' -> '*/' ;
```

This is the rule for Java-style comments that begin with ‘/*’ and end with ‘*/’.

Negated Token

All the tokens explained above can be inverted using a preceding explanation mark:

```
terminal ML_COMMENT : '/*' (!'*/')+ ;
```

Rule Calls

Rules can refer to other rules. This is done by writing the name of the rule to be called. We refer to this as rule calls. Rule calls in terminal rules can only point to terminal rules.

Example:

```
terminal QUALIFIED_NAME : ID ( '.' ID ) * ;
```

Alternatives

Using alternatives one can state multiple different alternatives. For instance, the whitespace rule uses alternatives like this:

```
terminal WS : ( ' ' | '\t' | '\r' | '\n' ) + ;
```

That is a WS can be made of one or more whitespace characters (including ' ', '\t', '\r', '\n')

Groups

Finally, if you put tokens one after another, the whole sequence is referred to as a group. Example:

```
terminal FOO : '0x' ( '0' .. '7' ) ( '0' .. '9' | 'A' .. 'F' ) ;
```

That is the 4-digit hexadecimal code of ascii characters.

2.2.4. Parser Rules

The parser reads in a sequence of terminals and walks through the parser rules. Hence a parser rule – contrary to a terminal rule – does not produce a single terminal token but a tree of non-terminal and terminal tokens. They lead to a so called parse tree (in Xtext it is also referred as node model). Furthermore, parser rules are handled as kind of a building plan for the creation EObjects that form the semantic model (the linked abstract syntax graph or AST). Due to this fact, parser rules are even called production rules. The different constructs like actions and assignments are used to derive types and initialize the semantic objects accordingly.

2.2.4.1. Extended Backus-Naur Form expressions

Not all the expressions that are available in terminal rules can be used in parser rules. Character ranges, wildcards, the until token and the negation are only available for terminal rules.

The elements that are available in parser rules as well as in terminal rules are

1. [groups](#),
2. [alternatives](#),
3. [keywords](#) and
4. [rule calls](#).

In addition to these elements, there are some expressions used to direct how the AST is constructed, which are listed and explained in the following.

Assignments

Assignments are used to assign the parsed information to a feature of the current object. The type of the current object, its EClass, is specified by the return type of the parser rule. If it is not explicitly stated it is implied that the type's name equals the rule's name. The type of the feature is inferred from the right hand side of the assignment.

Example:

```
State :
  'state' name=ID
    ( 'actions' '{' (actions+=[Command])+ '}' ) ?
    (transitions+=Transition)*
  'end' ;
```

The syntactic declaration for states in the state machine example starts with a keyword 'state' followed by an assignment :

```
name=ID
```

The left hand side refers to a feature 'name' of the current object (which has the EClass 'State' in this case). The right hand side can be a rule call, a keyword, a cross reference (explained later) or even an alternative comprised by the former. The type of the feature needs to be compatible with the type of the expression on the right. As ID returns an EString the feature 'name' needs to be of type EString as well.

Assignment Operators

There are three different assignment operators, each with different semantics.

1. The simple equal sign "=" is the straight forward assignment, and used for features which take only one element.
2. The "+=" sign (the add operator) expects a multi valued feature and adds the value on the right hand to that feature, which is a list feature.
3. The "?=" sign (boolean assignment operator) expects a feature of type EBoolean and sets it to true if the right hand side was consumed independently from the concrete value of the right hand side..

Cross References

A unique feature of Xtext is the ability to declare cross links in the grammar. In traditional compiler construction the cross links are not established during parsing but in a later linking phase. This is the same in Xtext, but we allow to specify cross link information in the grammar. This information is used by the linker. The syntax for cross links is:

```
CrossReference :
  '[' type=TypeRef ( '|' ^terminal=CrossReferenceableTerminal )? ']'
;
```

For example, the transition is made up of two cross references, pointing to an event and a state:

```
Transition :
  event=[Event] '=>' state=[State];
```

It is important to understand that the text between the square brackets does not refer to another rule, but to a type! This is sometimes confusing, because one usually uses the same name for the rules and the types. That is if we had named the type for events differently like in the following the cross references needs to be adapted as well:

```
Transition :
  event=[MyEvent] '=>' state=[State];

Event returns MyEvent : ....;
```

Looking at the syntax definition of cross references, there is an optional part starting with a vertical bar (pipe) followed by 'CrossReferenceableTerminal'. This is the part describing the concrete text, from which the crosslink later should be established. If the terminal is omitted, it is expected to be an ID.

You may even use alternatives as the referencable terminal. This way, either an ID or a STRING may be used as the referencable terminal, as it is possible in many SQL dialects.

```
TableRef: table=[Table] ( ID | STRING );
```

Have a look at the [linking section](#) in order to understand how linking is done.

Simple Actions

By default the object to be returned by a parser rule is created lazily on the first assignment. Then the type of the EObject to be created is determined from the specified return type (or the rule name if no explicit return type is specified). With Actions however, creation of EObject can be made explicit. Xtext supports two kinds of Actions:

1. simple actions and
2. assigned actions.

If at some point you want to enforce creation of a specific type you can use alternatives or simple actions. In the following example TypeB must be a subtype of TypeA. An expression `A ident` should create an instance of TypeA, whereas `B ident` should instantiate TypeB.

Example with alternatives:

```
MyRule returns TypeA :
  "A" name=ID |
  MyOtherRule;

MyOtherRule returns TypeB :
  "B" name = ID;
```

Example with simple actions:

```
MyRule returns TypeA :
  "A" name=ID |
  "B" {TypeB} name=ID;
```

Generally speaking, the instance is created as soon as the parser hits the first assignment. However, Actions allow to explicitly instantiate any EObject. The notation `{TypeB}` will create an instance of TypeB and assign it to the result of the parser rule. This allows parser rules without any assignment and object creation without the need to introduce stub-rules.

Unassigned rule calls

We previously explained, that the EObject to be returned is created lazily when the first assignment occurs or when a simple action is evaluated. There is another way one can set the EObject to be returned, which we call an “unassigned rule call”.

Unassigned rule calls (the name suggests it) are rule calls to other parser rules, which are not used within an assignment. If there is no feature the returned value shall be assigned to, the value is assigned to the “to-be-returned” reference.

With unassigned rule calls one can, for instance, create rules which just dispatch between several other rules:

```
AbstractToken :
  TokenA |
  TokenB |
  TokenC;
```

As AbstractToken could possibly return an instance of TokenA, TokenB or TokenC its type must be a super type of these types.

It is now for instance as well possible to further change the state of the AST element by assigning additional things.

Example:

```
AbstractToken :
  (TokenA |
   TokenB |
   TokenC ) (cardinality=('?'|'+'|'*'))?;
```

This way the cardinality is optional (last question mark) and can be represented by a question mark, a plus, or an asterisk. It will be assigned to either an EObject of type TokenA, TokenB or TokenC which are all subtypes of AbstractToken. The rule in this example will never create an instance of AbstractToken directly.

Assigned Actions

LL parsing has some significant advantages over LR algorithms. The most important ones for Xtext are, that the generated code is much simpler to understand and debug and that it is easier to recover from

errors and especially Antlr has a very nice generic error recovery mechanism. This allows to construct an AST even if there are syntactic errors in the text. You wouldn't get any of the nice IDE features as soon as there is one little error, if we hadn't error recovery.

However, LL also has some drawbacks. The most important one is that it does not allow left recursive grammars. For instance, the following is not allowed in LL based grammars, because "Expression '+' Expression" is left recursive:

```
Expression :
  Expression '+' Expression |
  '(' Expression ')'
  INT;
```

Instead one has to rewrite such things by "left-factoring" it:

```
Expression :
  TerminalExpression ('+' Expression)?;

TerminalExpression :
  '(' Expression ')' |
  INT
```

In practice this is always the same pattern and therefore not that problematic. However, by simply applying the Xtext AST construction features we've covered so far, a grammar ...

```
Expression :
  {Operation} left=TerminalExpression (op='+' right=Expression)?;

TerminalExpression returns Expression:
  '(' Expression ')' |
  {IntLiteral} value=INT;
```

... would result in unwanted elements in the AST. For instance the expression "(42)" would result in a tree like this:

```
Operation {
  left=Operation {
    left=IntLiteral {
      value=42
    }
  }
}
```

Typically one would only want to have one instance of `IntLiteral` instead.

One can solve this problem using a combination of unassigned rule calls and assigned actions:

```
Expression :
  TerminalExpression ({Operation.left=current}
    op='+' right=Expression)?;

TerminalExpression returns Expression:
  '(' Expression ')' |
  {IntLiteral} value=INT;
```

In the example above `{Operation.left=current}` is a so called tree rewrite action, which creates a new instance of the stated EClass (`Operation` in this case) and assigns the element currently to-be-returned (`current` variable) to a feature of the newly created object (in this case feature 'left' of the `Operation` instance). In Java these semantics could be expressed as:

```
Operation temp = new Operation();
temp.setLeft(current);
current = temp;
```

2.2.5. Hidden terminal symbols

Because parser rules describe not a single token, but a sequence of patterns in the input, it is necessary to define the interesting parts of the input. Xtext introduces the concept of hidden tokens to handle semantically unimportant things like whitespaces, comments, etc. in the input sequence gracefully. It is possible to define a set of terminal symbols, that are hidden from the parser rules and automatically skipped when they are recognized. Nevertheless, they are transparently woven into the node model, but not relevant for the semantic model.

Hidden terminals may (or may not) appear between any other terminals in any cardinality. They can be described per rule or for the whole grammar. When [reusing a single grammar](#) its definition of hidden tokens is reused as well. The grammar `org.eclipse.xtext.common.Terminals` comes with a reasonable default and hides all comments and whitespace from the parser rules.

If a rule defines hidden symbols, you can think of a kind of scope that is automatically introduced. Any rule that is called from the declaring rule uses the same hidden terminals as the calling rule, unless it defines other hidden tokens itself.

```
Person hidden(WS, ML_COMMENT, SL_COMMENT):
    name=fullname age=INT ';'

Fullname:
    (firstname=ID)? lastname=ID;
```

The sample rule “Person” defines multiline comments (ML_COMMENT), single-line comments (SL_COMMENT), and whitespaces (WS) to be allowed between the ‘Fullname’ and the ‘age’. Because the rule ‘Fullname’ does not introduce another set of hidden terminals, it allows the same symbols to appear between ‘firstname’ and ‘lastname’ as the calling rule ‘Person’. Thus, the following input is perfectly valid for the given grammar snippet:

```
John /* comment */ Smith // line comment
    /* comment */
    42      ;
```

A list of all default terminals like WS can be found in section [Grammar Mixins](#).

2.2.6. Datatype rules

Datatype rules are parsing-phase rules, which create instances of `EDataType` instead of `EClass`. Thinking about it, they are quite similar to terminal rules. The nice thing about datatype rules is that they are actually parser rules and are therefore

1. context sensitive and
2. allow for use of hidden tokens.

If you, for instance, want to define a rule to consume Java-like qualified names (e.g. “foo.bar.Baz”) you could write:

```
QualifiedName :
    ID ('.' ID)*;
```

Which looks similar to the terminal rule we’ve defined above in order to explain rule calls. However, the difference is that because it is a parser rule and therefore only valid in certain contexts, it won’t conflict with the rule ID. If you had defined it as a terminal rule, it would possibly hide the ID rule.

In addition when this has been defined as a datatype rule, it is allowed to use hidden tokens (e.g. “/* comment */”) between the IDs and dots (e.g. `foo/* comment */. bar . Baz`)

Return types can be specified in the same way as in terminal rules:

```
QualifiedName returns ecore::EString : ID ('.' ID)*;
```

Note that if a rule does not call another parser rule and does neither contain any actions nor [assignments](#), it is considered to be a datatype rule and the datatype `EString` is implied if none has been explicitly declared.

For conversion again value converters are responsible (cf. [value converters](#)).

2.2.7. Enum Rules

Enum rules return enumeration literals from strings. They can be seen as a shortcut for datatype rules with specific value converters. The main advantage of enum rules is their simplicity, typesafety and therefore nice validation. Furthermore it is possible to infer enums and their respective literals during the metamodel transformation.

If you want to define a ChangeKind org.eclipse.emf.ecore.change/model/Change.ecore with 'ADD', 'MOVE' and 'REMOVE' you could write:

```
enum ChangeKind :
  ADD | MOVE | REMOVE;
```

It is even possible to use alternative literals for your enums or reference an enum value twice:

```
enum ChangeKind :
  ADD = 'add' | ADD = '+' |
  MOVE = 'move' | MOVE = '->' |
  REMOVE = 'remove' | REMOVE = '-';
```

Please note, that Ecore does not support unset values for enums. If you formulate a grammar like

```
Element: "element" name=ID (value=SomeEnum)?;
```

with the input of

```
element Foo
```

the resulting value of the element `Foo` will hold the enum value with the internal representation of 0. When generating the EPackage from your grammar this will be the first literal you define. As a workaround you could introduce a dedicated none-value or order the enums accordingly. Note that it is not possible to define an enum literal with an empty textual representation.

```
enum Visibility: package | private | protected | public;
```

You can overcome this by modifying the inferred meta model through a [model to model transformation](#).

2.3. Meta-Model inference

The meta model of a textual language describes the structure of its abstract syntax trees (AST).

Xtext uses Ecore EPackages to define meta models. Meta models are declared to be either inferred (generated) from the grammar or imported. By using the 'generate' directive, one tells Xtext to derive an EPackage from the grammar.

2.3.1. Type and Package Generation

Xtext creates

- an EPackage
 - for each generate-package declaration. After the directive "generate" a list of parameters follows. The 'name' of the EPackage will be set to the first parameter, its 'nsURI' to the second parameter. An optional alias as the third parameter allows to distinguish generated EPackages later. Only one generated package declaration per alias is allowed.
- an EClass
 - for each return type of a parser rule. If a parser rule does not define a return type, an implicit one with the same name as the rule itself is assumed. You can specify more than one rule that return the same type but only one EClass will be generated.
 - for each type defined in an action or a cross-reference.
- an EEnum

- for each return type of an enum rule.
- an EDatatype
 - for each return type of a terminal rule or a datatype rule.

All EClasses, EEnums and EDatatypes are added to the EPackage referred to by the alias provided in the type reference they were created from.

2.3.2. Feature and Type Hierarchy Generation

While walking through the grammar, the algorithm keeps track of a set of the currently possible return types to add features to.

- Entering a parser rule the set contains only the return type of the rule.
- Entering a group in an alternative the set is reset to the same state it was in when entering the first group of this alternative.
- Leaving an alternative the set contains the union of all types at the end of each of its groups.
- After an optional element, the set is reset to the same state it was before entering it.
- After a mandatory (non-optional) rule call or mandatory action the set contains only the return type of the called rule or action.
- An optional rule call does not modify the set.
- A rule call is optional, if its cardinality is '?' or '*'.

While iterating the parser rules Xtext creates

- an EAttribute in each current return type
 - of type EBoolean for each feature assignment using the '?=' operator. No further EReferences or EAttributes will be generated from this assignment.
 - for each assignment with the '=' or '+=' operator calling a terminal rule. Its type will be the return type of the called rule.
- an EReference in each current return type
 - for each assignment with the '=' or '+=' operator in a parser rule calling a parser rule. The EReference type will be the return type of the called parser rule.
 - for each action. The reference's type will be set to the return type of the current calling rule.

Each EAttribute or EReference takes its name from the assignment/action that caused it. Multiplicities will be 0...1 for assignments with the '=' operator and 0...* for assignments with the '+=' operator.

Furthermore, each type that is added to the currently possible return types automatically inherits from the current return type of the parser rule. You can specify additional common supertypes by means of "artificial" parser rules, that are never called, e.g.

```
CommonSuperType:
  SubTypeA | SubTypeB | SubTypeC;
```

2.3.3. Enum Literal Generation

For each alternative defined in an enum rule, the transformer creates an enum literal, when another with the same name cannot be found. The 'literal' property of the generated enum literal is set to the right hand side of the declaration. If it is omitted, you'll get an enum literal with equal 'name' and 'literal' attributes.

```
enum MyGeneratedEnum:
  NAME = 'literal' | EQUAL_NAME_AND_LITERAL;
```

2.3.4. Feature Normalization

Next the generator examines all generated EClasses and lifts up similar features to supertypes if there is more than one subtype and the feature is defined in every subtypes. This does even work for multiple supertypes.

2.3.5. Customized Post Processing

As a last step, the generator invokes the post processor for every generated meta model. The post processor expects an Xtend file with name `MyDslPostProcessor.ext` (if the name of the grammar file is `MyDsl.xtext`) in the same folder as the grammar file. Further, for a successful invocation, the Xtend file must declare an extension with signature `process(xtext::GeneratedMetamodel)`. E.g.

```
process(xtext::GeneratedMetamodel this) :  
    process(ePackage)  
;  
  
process(ecore::EPackage this) :  
    ...  
;
```

The invoked extension can then augment the generated Ecore model in place. Some typical use cases are to:

- set default values for attributes
- add container references as opposites of existing containment references
- add operations with implementation (using a body annotation)

Great care must be taken not to modify the meta model in a way preventing the Xtext parser from working correctly (e.g. removing or renaming model elements).

2.3.6. Error Conditions

The following conditions cause an error

- An EAttribute or EReference has two different types or different cardinality.
- There are an EAttribute and an EReference with the same name in the same EClass.
- There is a cycle in the type hierarchy.
- An new EAttribute, EReference or supertype is added to an imported type.
- An EClass is added to an imported EPackage.
- An undeclared alias is used.
- An imported metamodel cannot be loaded.

2.4. Importing existing Meta Models

With the import directive in Xtext you can refer to existing Ecore meta models and reuse the types that are declared in an EPackage. Xtext uses this technique itself to leverage Ecore datatypes.

```
import "http://www.eclipse.org/emf/2002/Ecore" as ecore
```

Specify an explicit return type to reuse such imported types. Note that this even works for terminal rules.

```
terminal INT returns ecore::EInt : ('0'..'9')+;
```

2.5. Grammar Mixins

Xtext supports the reuse of existing grammars. Grammars that are created via the Xtext wizard use `org.eclipse.xtext.common.Terminals` by default which introduces a common set of terminal rules and defines reasonable defaults for hidden terminals.

```
grammar org.xtext.example.MyDsl with org.eclipse.xtext.common.Terminals  
  
generate myDsl "http://www.xtext.org/example/MyDsl"  
  
....
```

Mixing in another grammar makes the rules defined in that grammar referable. It is also possible to overwrite rules from the used grammar.

Example :

```
grammar my.SuperGrammar
...
RuleA : "a" stuff=RuleB;
RuleB : "{" name=ID "}";

grammar my.SubGrammar with my.SuperGrammar

Model : (ruleAs+=RuleA)*;

// overrides my.SuperGrammar.RuleB
RuleB : '[' name=ID ']';
```

Note that declared terminal rules always get a higher priority then imported terminal rules.

2.6. Default tokens

Xtext ships with a default set of predefined, reasonable and often required terminal rules. This grammar is defined as follows:

```
grammar org.eclipse.xtext.common.Terminals
    hidden(WS, ML_COMMENT, SL_COMMENT)

import "http://www.eclipse.org/emf/2002/Ecore" as.ecore

terminal ID :
    '^?('a'..'z'|'A'..'Z'|'_' ) ('a'..'z'|'A'..'Z'|'_'|'0'..'9')* ;
terminal INT returns.ecore::EInt: ('0'..'9')+ ;
terminal STRING :
    '"' ( '\\' ('b'|'t'|'n'|'f'|'r'|'"'|'\n'|'\r') | !('\\'|'"') ) * '"' |
    "'" ( '\\' ('b'|'t'|'n'|'f'|'r'|'"'|'\n'|'\r') | !('\\'|'"') ) * "'"
    ;
terminal ML_COMMENT : '/*' -> '*/' ;
terminal SL_COMMENT : '// ' !('\n'|'\r')* ('\r'? '\n')? ;

terminal WS : (' '|'\t'|'\r'|'\n')+ ;

terminal ANY_OTHER: . ;
```

Chapter 3. Configuration

3.1. The Generator

Xtext provides lots of generic implementations for your language's infrastructure but also uses code generation to generate some of the components. Those generated components are for instance the parser, the serializer, the Ecore model and a couple of convenient base classes for content assist etc.

The generator also contributes to shared project resources such as the `plugin.xml`, `Manifest.MF` and the [Guice modules](#).

Xtext's generator leverages the [modeling workflow engine \(MWE\)](#) from EMFT.

3.1.1. A short introduction to MWE

The nice thing about MWE is that it just instantiates java classes and the configuration is done through setter and adder methods. Given the following Java class :

```
package foo;

public class Person {

    private String name;

    public void setName(String name) {
        this.name = name;
    }

    private final List<Person> children = new ArrayList<Person>();

    public void addChild(Person child) {
        this.children.add(child);
    }
}
```

one can create a family tree like this:

```
<x class="foo.Person">
  <name value="Grandpa" />
  <child class="foo.Person" name="Father">
    <child name="Son" />
  </child>
</x>
```

These couple of lines will, when interpreted by MWE, result in an object tree consisting of three instances of `foo.Person`:

The root element can have an arbitrary name, with one exception: If the name is `workflow` and no `class` attribute is provided, it is assumed that an instance of `org.eclipse.emf.mwe.internal.core.Workflow` shall be instantiated. This instance will be the root of a workflow model used in generator workflow configurations. However, as you can see in the example above one can instantiate arbitrary Java object models. This is conceptually very close to the dependency injection and the XML language in the [Spring Framework](#).

As explained above the `x` is ignored in this case. The attribute `class` tells MWE which class to use in order to create the object node. That created object is populated according to the XML description: For each XML attribute MWE calls a corresponding setter or adder method passing in the value (There

are configurable value converters, but usually Boolean and String is all you need). The same procedure is applied for each child element. In the case of XML elements a single attribute value is used and interpreted as if there was an attribute in the parent element. That is:

```
<foo><name value="bar" /></foo>
```

means the same as

```
<foo name="bar" />
```

Obviously the latter is far more readable and should be preferred. However, as soon as you want to add multiple values to the same ‘adder’ method you will need to use the first syntax because you cannot define the same attribute twice in XML.

If an element does not have an attribute value, the engine looks for an attribute called class. If it finds one, the class is instantiated by means of the the default constructor (there is no support for factories as of now.). If not, the class is inferred by looking at the argument’s type of the current setter method.

This is why it is ok to write:

```
<child name="Son" />
```

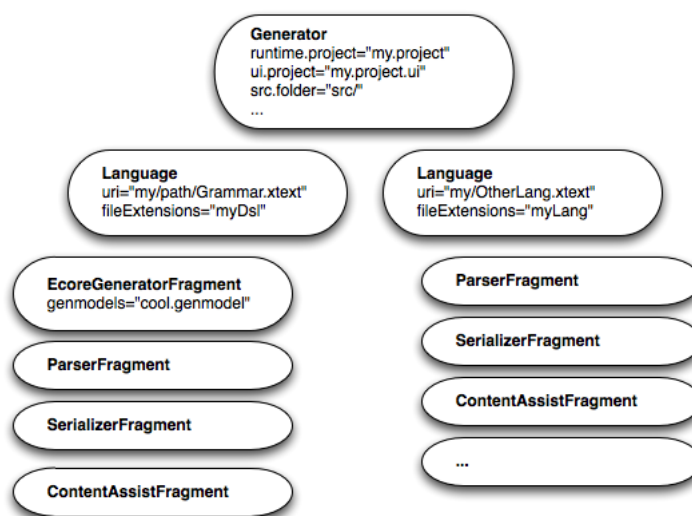

The addChild method takes a foo.Person as an argument. As this is a concrete class which has a default constructor it can be instantiated.

Tip Whenever you are in an *.mwe file and wonder what kind of configuration the underlying component may accept: Just use JDT’s open type action (CTRL+Shift+T) open the source file of the class in question, use the outline view (CTRL+O CTRL+O) and type ‘set’ or ‘add’ and you will see the available modifiers. Note that we plan to replace the XML syntax with an Xtext-based implementation as soon as possible.

So this is the basic idea of the MWE language. There are of course a couple of additional concepts and features in the language and we also have not yet talked about the runtime workflow model. Please consult the reference documentation (available through Eclipse help) for additional information.

3.1.2. General Architecture

Now that you know a bit about MWE, you are ready to learn about the concepts and architecture of Xtext’s generator. An instance of Xtext’s generator is configured with general information about source folders and projects and consists of any number of language configurations. For each language configuration a URI pointing to its grammar file and the file extensions for the DSL must be provided. In addition, a language is configured with a list of [IGeneratorFragments](#). The whole generator is composed of theses fragments. We have fragments for generating parsers, the serializer, the EMF code, the outline view, etc.

3.1.2.1. Generator Fragments

Each fragment gets the grammar of the language as an EMF model passed in. A fragment is able to generate code in one of the configured locations and contribute to several shared

artifacts. The main interface [IGeneratorFragment](#) is supported by a convenient abstract base class [AbstractGeneratorFragment](#), which by default delegates to an Xpand template with the same qualified name as the class and delegates some of the calls to Xpand template definitions.

We suggest to have a look at the fragment we have written for label providers ([LabelProviderFragment](#)). It is pretty trivial and at the same time uses the most important call backs. In addition, the structure is not cluttered with too much extra noise so that the whole package (as of Xtext 0.7.0) can serve as a template to write your own fragment.

3.1.2.2. Configuration

As already explained we use MWE from EMFT in order to build, configure and execute this structure of components. In the following we see an exemplary Xtext generator configuration written in MWE configuration code:

```
<workflow>
  <property file="org.xtext/example/GenerateMyDsl.properties"/>

  <property name="runtimeProject" value="../${projectName}"/>

  <bean class="org.eclipse.emf.mwe.utils.StandaloneSetup"
    platformUri="${runtimeProject}/../"/>

  <component class="org.eclipse.emf.mwe.utils.DirectoryCleaner"
    directory="${runtimeProject}/src-gen"/>
  <component class="org.eclipse.emf.mwe.utils.DirectoryCleaner"
    directory="${runtimeProject}.ui/src-gen"/>

  <component class="org.eclipse.xtext.generator.Generator">
    <pathRtProject value="${runtimeProject}"/>
    <pathUiProject value="${runtimeProject}.ui"/>
    <projectNameRt value="${projectName}"/>
    <projectNameUi value="${projectName}.ui"/>

    <language uri="${grammarURI}" fileExtensions="${file.extensions}">
      <!-- Java API to access grammar elements (required by several other fragments) -->
      <fragment class="org.eclipse.xtext.generator.grammarAccess.GrammarAccessFragment"/>

      <!-- a lot more simple fragments -->
      <!-- ... -->

      <!-- a sample fragment with a property -->
      <fragment class="org.eclipse.xtext.generator.validation.JavaValidatorFragment">
        <composedCheck value="org.eclipse.xtext.validation.ImportUriValidator"/>
      </fragment>

      <!-- java-based API for content assistance -->
      <fragment class="org.eclipse.xtext.ui.generator.contentAssist.JavaBasedContentAssistFra
    </language>
  </component>
</workflow>
```

Here the root element is a workflow which accepts *bean*s and *component*s. The `<property/>` element is a first class concept of MWE's configuration language and essentially acts as a preprocessor, which replaces all occurrences of `${propertyName}` with the given value. Property declarations can be inlined (`<property name="foo" value="bar"/>`) or by means of a property file import (`<property file="foo.properties"/>`) which is performed before the actual tree is created. In this example we first import a properties file and after that declare a property `runtimeProject` which already uses a property imported from the file previously.

The method `Workflow.setBean()` does nothing but provides a means to apply global side-effects, which unfortunately is required by some projects. In this example we do a so called *EMF stand alone setup*. This class initializes a bunch of things for a non-Equinox environment that are otherwise configured by means of extension points, e.g. EMF's `EPackage.Registry`.

Following the `<bean/>` element there are three `<component/>` elements. The `Workflow.addComponent()` method awaits instances of `IWorkflowComponent`, which is the primary concept of MWE's workflow model. Xtext's generator is an instance of `IWorkflowComponent` and can therefore be used within MWE workflows.

3.1.3. Standard generator fragments

In the following the most important standard generator fragments are listed. Please refer to the Javadocs for more documentation.

Class	Generated Artifacts
EcoreGeneratorFragment	EMF code for generated models
XtextAntlrGeneratorFragment	ANTLR grammar, parser, lexer and related services.
GrammarAccessFragment	Access to the grammar
ResourceFactoryFragment	EMF resource factory
ParseTreeConstructorFragment	Model-to-text serialization
JavaScopingFragment	Java-based scoping
JavaValidatorFragment	Java-based model validation
CheckFragment	Xpand/Check-based model validation
FormatterFragment	Code formatter
LabelProviderFragment	Label provider
OutlineNodeAdapterFactoryFragment	Outline view configuration
TransformerFragment	Outline view configuration
JavaBasedContentAssistFragment	Java-based content assist
XtextAntlrUiGeneratorFragment	Content assist helper based on ANTLR
SimpleProjectWizardFragment	New project wizard

Important Due to IP-Problems with the code generator shipped with ANTLR 3 we're not allowed to ship this fragment at Eclipse. Therefore you'll have to download it separately from <http://download.itemis.com> or use the updatesite at <http://download.itemis.com/updates/>.

3.2. Dependency Injection in Xtext with Google Guice

In Xtext, there are many state-less Java classes which implement logic, behavior, or supply configuration. These classes implement Java interfaces and are typically only supposed to be accessed through these interfaces, which makes their implementations interchangeable. This is where Xtext utilizes [Google Guice](#):

- Guice manages the instantiation of the classes: instead of constructing a class with `new`, the `@Inject` annotation instructs Guice to supply an object for a certain interface. Such an object is called [Service](#).
- Guice allows to configure which implementations are to be supplied for which interface. This configuration consists of so-called [modules](#).

3.2.1. Services

The most parts of Xtext are implemented as *services*. A service is a state-less object which implements a certain interface and which is managed by Guice.

Xtext ships with generic default implementations for the most services or runs [generator fragments](#) to automatically generate service implementations from a grammar. Thereby, Xtext strives to provide meaningful implementations out of the box and to allow customization wherever needed. Developers are encouraged to sub-class existing services and configure them for their languages using [modules](#).

When Guice instantiates a service, it also supplies this instance with all its dependent services. All a service does is to request “some implementation for a certain interface” using the `@Inject`-annotation. Based on the [modules](#) Guice decides which class to instantiate or which object to reuse.

For example, Guice can automatically initialize member variables with the needed services.

```
public class MyLanguageLinker extends Linker {

    @Inject
    private IScopeProvider scopeProvider;

    @Inject(optional=true)
    private IText2EcorePostProcessor postProcessor;

    (...)
}
```

Furthermore, Guice can pass the needed services as constructor parameters.

```
public class MyLanguageGrammarAccess implements IGrammarAccess {

    private final GrammarProvider grammarProvider;

    private TerminalsGrammarAccess gaTerminals;

    @Inject
    public MyLanguageGrammarAccess(GrammarProvider grammarProvider,
        TerminalsGrammarAccess gaTerminals) {
        this.grammarProvider = grammarProvider;
        this.gaTerminals = gaTerminals;
    }

    (...)
}
```

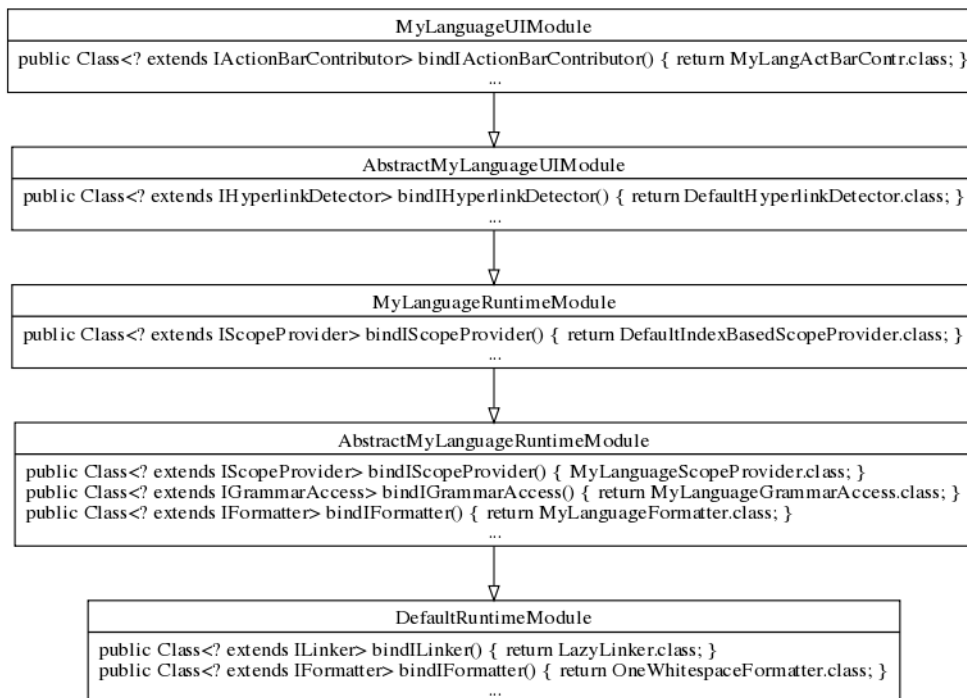

For further details, please refer to the [Google Guice Documentation](#)

3.2.2. Modules

The configuration of services for an Xtext-Language is done via modules:

- Modules map (bind) Java-Interfaces to their Implementation-Classes.
- A module itself is a Java-Class.
- Modules can inherit from each other and override bindings that are declared in super-modules.
- In Xtext, there is a [generic default module](#) for all languages, there are automatically [generated modules](#) and there are modules which are [intended to be customized manually](#).
- Furthermore, Xtext distinguishes between modules for runtime-services and modules related to service needed for the user interface.

In total, this leads to a total of five modules for a typical Xtext Language. They are visualized in the image below. The image is further explained in the following subsections.

3.2.2.1. Modules intended for customization

When the [generator](#) runs the first time, it creates two modules named `RuntimeModule` and `UIModule`. They are placed in language's root-package the `src/-`folder of the language's runtime-project and the language's UI-project. Both are initially empty and will never be overwritten by the generator. They are [intended for customization](#). By default, they extend a [generated module](#).

3.2.2.2. Generated Modules

The fully generated modules (never touch them!) are called `Abstract[MyLanguage]RuntimeModule` and `Abstract[MyLanguage]UIModule` respectively. They contain all components which have been generated specifically for the language at hand. What goes into these modules depends on how your generator is configured.

3.2.2.3. Default Modules

Finally the fully generated modules extend the [DefaultRuntimeModule](#), which contains all the default configuration. The default configuration consists of all components for which we have generic default implementations (interpreting as opposed to generated).

3.2.2.4. Changing Configuration

We use the primary modules (`[MyLanguage]RuntimeModule` and `[MyLanguage]UIModule`) in order to change the configuration. The class is initially empty and has been generated to allow customization.

In order to provide a simple and convenient way, in TMF Xtext every module extends `AbstractXtextModule`. This class allows to write bindings like this:

```
public Class<? extends MyInterface> bind[anyname]() {
    return MyInterfaceImpl.class;
}
```

Such a method will be interpreted as a binding from `MyInterface` to `MyInterfaceImpl`. Note that you simply have to override a method from a super class (e.g. from the generated or default module) in order to change the respective binding. For example, in the picture above, the `DefaultRuntimeModule` configures the [IFormatter](#) to be implemented by the [OneWhitespaceFormatter](#) and `AbstractMyLanguageModule` overrides this binding by binding the [IFormatter](#) to `MyLanguageFormatter`. Although this is a convenient and simple way, you have of course also the full power of Guice, i.e. you can override the Guice method `void bind(Binding)` and do what every you want.

Chapter 4. Runtime Concepts

TMF Xtext itself and every language infrastructure developed with TMF Xtext is configured and wired-up using dependency injection (DI).

We use Google Guice as the underlying framework, and haven't built much on top of it as it pretty much does what we need. So instead of describing how google guice works, we refer to the website, where additional information can be found: <http://code.google.com/p/google-guice/>.

Using DI allows everyone to set up and change all components. This does not mean that everything which gets configured using DI (we use it a lot) is automatically public API. But we don't forbid use of non-public API, as we think you should decide, if you want to rely on stable API only or use things which might be changed (further enhanced ;-)) in future. See [Xtext API Documentation](#).

4.1. Runtime setup (ISetup)

For each language there is an implementation of `ISetup` generated. It implements a method called `doSetup()`, which can be called to do the initialization of the language infrastructure.

This class is intended to be used for runtime and unit testing, only.

The setup method returns an `Injector`, which can further be used to obtain a parser, etc.

The setup method also registers the `ResourceFactory` and generated `EPackage` with the respective global registries provided by EMF.

So basically you can just run the setup and start using EMF API to load and store models of your language.

4.2. Setup within Eclipse / Equinox

Within Eclipse we have a generated `Activator`, which creates a guice injector using the modules. In addition an `IExecutableExtensionFactory` is generated for each language, which is used to create `ExecutableExtensions`. This means that everything which is created via extension points is managed by guice as well, i.e. you can declare dependencies and get them injected upon creation.

The only thing you have to do in order to use this factory is to prefix the class with the factory (`[MyLanguageName]ExecutableExtensionFactory`) name followed by a colon.

```
<extension
  point="org.eclipse.ui.editors">
  <editor
    class="<MyLanguageName>ExecutableExtensionFactory:
      org.eclipse.xtext.ui.core.editor.XtextEditor"
    contributorClass=
      "org.eclipse.ui.editors.text.TextEditorActionContributor"
    default="true"
    extensions="ecoredsl"
    id="org.eclipse.xtext.example.EcoreDsl"
    name="EcoreDsl Editor">
  </editor>
</extension>
```

4.3. Validation

Validation (a.k.a Static Analysis) is one of the most interesting aspects when developing a programming language. The users of your languages will be grateful if they get informative feedback as they type. In Xtext there are basically three different kinds of validation

4.3.1. Syntactical Validation

The syntactical correctness of any textual input is validated automatically by the parser. The error messages are generated by the underlying parser technology and cannot be customized using a general hook. Any syntax errors can be retrieved from the Resource using the common EMF API:

- `org.eclipse.emf.ecore.resource.Resource.getErrors()`
- `org.eclipse.emf.ecore.resource.Resource.getWarnings()`

4.3.2. Cross-link Validation

Any broken cross-links can be checked generically. As cross-link resolution is done lazily (see linking), any broken links are resolved lazy as well. If you want to validate whether all links are valid, you'll have to navigate through the model so that all proxies get resolved. This is done automatically in the editor.

Any unresolvable cross-links will be reported through:

- `org.eclipse.emf.ecore.resource.Resource.getErrors()`
- `org.eclipse.emf.ecore.resource.Resource.getWarnings()`

4.3.3. Custom Validation

In addition to the afore mentioned kinds of validations, which are more or less done automatically, you can specify additional constraints specific for your.ecore model. We leverage existing EMF API (mainly EValidator) and have put some convenience stuff on top. Basically all you need to do is to make sure that an EValidator is registered for your EPackage. The registry for EValidators (`org.eclipse.emf.ecore.EValidator.Registry.INSTANCE`) can only be filled programatically, that means that there's no equinox extension point similar to the EPackage- and ResourceFactory registries.

For Xtext we provide a generator fragment for the convenient java-based EValidator API. Just add the following fragment to your generator configuration and you're good to go:

```
<fragment
class="org.eclipse.xtext.generator.validation.JavaValidatorFragment"/
>
```

The generator will provide you with two Java classes. An abstract class generated to `src-gen/` which extends the library class `AbstractDeclarativeValidator`. This one just registers the EPackages for which this validator contains constraints. The other class is a subclass of that abstract class and is generated to the `src/` folder in order to be edited by you. That's where you put the constraints in.

The purpose of the `AbstractDeclarativeValidator` is to allow you to write constraints in a (the name says it) declarative way. That is instead of writing exhaustive if else constructs or extending the generated EMF switch you just have to add the `@Check` annotation to any method and it will be invoked automatically when validation takes place. Moreover you can state for what type the respective constraints method is, just by declaring a typed parameter. This also lets you avoid any type casts. In addition to the reflective invocation of test methods the `AbstractDeclarative` provides a couple of convenience assertions.

All in all this is very similar to how JUnit work. Example:

```
public class DomainmodelJavaValidator extends AbstractDomainmodelJavaValidator {

    @Check
    public void checkTypeNameStartsWithCapital(Type type) {
        if (!Character.isUpperCase(type.getName().charAt(0)))
            warning("Name should start with a capital", DomainmodelPackage.TYPE__NAME);
    }
}
```

4.3.4. Validation with Check

In addition to the Java-based validation code you can use the language Check to implement validations against your model. To do so, you have to call the [CheckFragment](#) from your [generator](#). Please note, that you can combine both types of validations in your project.

```
<fragment
class="org.eclipse.xtext.generator.validation.CheckFragment"/>
```

After regenerating your language artifacts you will find three new files “YourLanguageChecks.chk”, “YourLanguageFastChecks.chk” and “YourLanguageExpensiveChecks.chk” in the src/ folder in the sub-package validation. The checks in these files will be executed when saving a file, while typing (FastChecks) or when triggering the validation explicitly (ExpensiveChecks). When using Check the validation of the previous chapter could be written like this.

```
context Type#name WARNING "Name should start with a capital":
    name.toFirstUpper() == name;
```

Each check works in a specific context (here: Type) and can further denote a feature to which a warning or error should be attached to (here: name). Each check could either be a WARNING or an ERROR with a given string to explain the situation. The essential part of each check is an invariant that must hold true for the given context. If it does not the check will produce an issue with the provided explanation.

Please read more about the Check language as well as the underlying Expression language at the [documentation of openArchitectureWare](#). Also, you will find an example on how to implement checks in each of the generated files.

4.4. Linking

The linking feature allows for specification of cross references within an Xtext grammar. The following things are needed for the linking:

1. declaration of a cross link in the grammar (at least in the meta model)
2. specification of linking semantics

4.4.1. Declaration of cross links

In the grammar a cross reference is specified using square brackets.

```
CrossReference :
    '[' ReferencedEClass ('|' terminal=AbstractTerminal)? '']'
```

Example:

```
ReferringType :
    'ref' referencedObject=[Entity|(ID|STRING)];
```

The meta model derivation would create an EClass ‘ReferringType’ with an EReference ‘referencedObject’ of type ‘Entity’ (containment=false). The referenced object would be identified either by an ID or a STRING and the surrounding information (see scoping).

Example: While parsing a given input string, say

```
ref Entity01
```

Xtext produces an instance of ‘ReferringType’. After this parsing step it enters the linking phase and tries to find an instance of ‘Entity’ using the parsed text ‘Entity01’. The input

```
ref "EntityWithf+<"
```

would work analogously. This is not an ID (umlauts are not allowed), but a STRING (as it is apparent from the quotation marks).

4.4.2. Specification of linking semantics

The default ILinker implementation installs EObject proxies for all crosslinks, which are then resolved on demand. The actual cross ref resolution is done in LazyLinkingResource.getEObject(String) and delegates to ILinkingService. Although the default linking behavior is appropriate in many cases there might be scenarios where this is not sufficient. For each grammar a linking service can be implemented/configured, which implements the following interface:

```

@Stable(since = "0.7.0", subClass = AbstractLinkingService.class)
public interface ILinkingService {

    /**
     * Returns all {@link EObject}s referenced by the given link text in the
     * given context. But does not set the references or modifies the passed
     * information somehow
     */
    List<EObject> getLinkedObjects(
        EObject context,
        EReference reference,
        AbstractNode node)
        throws IllegalNodeException;

    /**
     * Returns the textual representation of a given object as it would be
     * serialized in the given context.
     *
     * @param object
     * @param reference
     * @param context
     * @return the text representation.
     */
    String getLinkText(
        EObject object,
        EReference reference,
        EObject context);
}

```

The method `getLinkedObjects` is directly related to this topic whereas `getLinkText` addresses complementary functionality: it is used for Serialization.

A simple implementation of the linking service (`DefaultLinkingService`) is shipped with Xtext and is used for any grammar per default. It uses the default implementation of `IScopeProvider`.

4.4.3. Default linking semantics

The default implementation for all languages, looks within the current file for an `EObject` of the respective type ('Entity') which has a name attribute set to 'Entity01'.

Given the grammar :

```

Model : (stuff+=(Ref|Entity))*;
Ref : 'ref' referencedObject=[Entity|ID] ';;';
Entity : 'entity' name=ID ';;';

```

In the following model :

```

ref Entity01;
entity Entity01;

```

the ref would be linked to the declared entity (`entity Entity01;`).

4.4.3.1. Default Imports

There is a default implementation for inter-resource referencing, which as well uses convention. Each string in a model which is assigned to an `EAttribute` with the name 'importURI', will be interpreted as a URI and used to be loaded using the `ResourceSet` of the current `Resource`.

For example, given the following grammar :

```

Model : (imports+=Import)* (stuff+=(Ref|Entity))*;
Import : 'import' importURI=STRING ';;';
Ref : 'ref' referencedObject=[Entity|ID] ';;';
Entity : 'entity' name=ID ';;';

```

It would be possible to write three files using in that language where the first references the other two, like this:

```
//file model.dsl
import "model1.dsl";
import "model2.dsl";

ref Foo;
entity Bar;
```

```
//file model1.dsl
entity Stuff;
```

```
//file model2.dsl
entity Foo;
```

The resulting default scope list is as follows:

```
Scope (model.dsl) {
  parent : Scope (model1.dsl) {
    parent : Scope (model2.dsl) {}
  }
}
```

So, the outer scope is asked for an Entity named `Foo`, as it does not contain such a declaration itself its parent is asked and so on. The default implementation of `IScopeProvider` creates this kind of scope chain.

4.5. Scoping

An `IScopeProvider` is responsible for providing an `IScope` for a given `EObject` and `EReference` (declared or inherited by the object's `EClass`). The returned `IScope` should contain all target candidates for the given object and cross reference.

```
@Stable(since = "0.7.0", subClass = AbstractScopeProvider.class)
public interface IScopeProvider {

    /**
     * Returns a scope for the given context. The scope provides access to
     * the compatible visible EObjects for a given reference.
     *
     * @param context the element from which an element shall be referenced
     * @param reference the reference to be used to filter the elements.
     * @return {@link IScope} representing the inner most {@link IScope} for
     *         the passed context and reference.
     */
    public IScope getScope(EObject context, EReference reference);

    /**
     * Returns a scope for a given context. The scope contains any visible,
     * type-compatible element.
     * @param context the element from which an element shall be referenced
     * @param type the (super)type of the elements.
     * @return {@link IScope} representing the inner most {@link IScope} for
     *         the passed context and type.
     */
    public IScope getScope(EObject context, EClass type);
}
```

An `IScope` represents an element of a linked list of scopes. That means that a scope can be nested within an outer scope. For instance Java has multiple kinds of scopes (object scope, type scope, etc.).

For Java one would create the scope hierarchy as commented in the following example:

```
// file contents scope
import static my.Constants.STATIC;

public class ScopeExample { // class body scope
    private Object field = STATIC;

    private void method(String param) { // method body scope
        String localVar = "bar";
        innerBlock: { // block scope
            String innerScopeVar = "foo";
            Object field = innerScopeVar;
            // the scope hierarchy at this point would look like this:
            //blockScope{field,innerScopeVar}->
            //methodScope{localVar,param}->
            //classScope{field}-> ('field' is overlayed)
            //fileScope{STATIC}->
            //classpathScope{'all qualified names of accessible static fields'} ->
            //NULLSCOPE{}
            //
        }
        field.add(localVar);
    }
}
```

In fact the class path scope should also reflect the order of class path entries. For instance:

```
classpathScope{stuff from bin/}
-> classpathScope{stuff from foo.jar/}
-> ...
-> classpathScope{stuff from JRE System Library}
-> NULLSCOPE{}
```

Please find the motivation behind this and some additional details in [this blog post](#).

4.5.1. Declarative Scope Provider

As always there is an implementation allowing to specify scoping in a declarative way (extend `org.eclipse.xtext.scoping.impl.AbstractDeclarativeScopeProvider` for this purpose). It looks up methods which have either of the following two signatures:

```
IScope scope_<ContextReference>(<ContextType> ctx, EReference ref)
```

```
IScope scope_<TypeToReturn>(<ContextType> ctx, EClass type)
```

The former is used when evaluating the scope for a specific cross reference and here `<ContextReference>` corresponds to the name of this reference (prefixed with the name of the reference's declaring type and separated by an underscore). The `ref` parameter represents this cross reference.

The latter method signature is used when evaluating the scope of a given element type and is applicable to all cross references of that type. Here `<TypeToReturn>` is the name of that type which also corresponds to the `type` parameter.

So if you for example have a state machine with a *Transition* object owned by its source *State* and you want to compute all reachable states (i.e. potential target states), the corresponding method could be declared as follows (assuming the cross reference is declared by the *Transition* type and is called *target*):

```
IScope scope_Transition_target(Transition this, EReference ref)
```

If such a method does not exist, the implementation will try to find one for the context object's container. Thus in the example this would match a method with the same name but *State* as the type of the first parameter. It will keep on walking the containment hierarchy until a matching method is found. This container delegation allows to reuse the same scope definition for elements in different places of the containment hierarchy. Also it may make the method easier to implement as the elements comprising the scope are quite often owned or referenced by a container of the context object. In the example the *State* objects could for instance be owned by a containing *StateMachine* object.

If no method specific to the cross reference in question was found for any of the objects in the containment hierarchy, the implementation will start looking for methods matching the other signature (with the *EClass* parameter). Again it will first attempt matching the context object. Thus in the example the signature first matched would be:

```
IScope scope_State(Transition this, EClass type)
```

If no such method exists, the implementation will again try to find a method matching the context object's container objects. In the case of the state machine example you might want to declare the scope with available states at the state machine level:

```
IScope scope_State(StateMachine this, EClass type)
```

This scope can now be used for any cross references of type *State* for context objects owned by the state machine.

4.6. Value Converter

Value converters are registered to convert parsed text into a certain data type instance and back. The primary hook is called `org.eclipse.xtext.conversion.IValueConverterService` and the concrete implementation can be registered via the runtime Guice module (TODO reference to framework description).

4.6.1. Annotation based value converters

The most simple way to register additional value converters is to make use of `org.eclipse.xtext.conversion.impl.AbstractAnnotationBasedValueConverterService`, which allows to declaratively register `IValueConverter` via annotated methods.

The implementation for the default token grammar looks like

```
public class DefaultTerminalConverters
    extends AbstractAnnotationBasedValueConverterService {

    private Grammar grammar;

    @Inject
    public void setGrammar(IGrammarAccess grammarAccess) {
        this.grammar = grammarAccess.getGrammar();
    }

    protected Grammar getGrammar() {
        return grammar;
    }

    @ValueConverter(rule = "ID")
    public IValueConverter<String> ID() {
        return new AbstractNullSafeConverter<String>() {
            @Override
            protected String internalToValue(String string, AbstractNode node) {
                return string.startsWith("^") ? string.substring(1) : string;
            }

            @Override
            protected String internalToString(String value) {
                if (GrammarUtil.getAllKeywords(getGrammar()).contains(value)) {
                    return "^"+value;
                }
                return value;
            }
        };
    }

    ... some other value converter
}
```

If you use the common terminals grammar (`org.eclipse.xtext.common.Terminals`) you should subclass `DefaultTerminalConverters` and overwrite or add additional value converter by adding the respective methods.

Imagine, you would want to add a rule creating `BigDecimals`:

```
@ValueConverter(rule = "BIG_DECIMAL")
public IValueConverter<String> BIG_DECIMAL() {
    return new AbstractToStringConverter<BigDecimal>() {
        @Override
        protected BigDecimal internalToValue(String string, AbstractNode node) {
            return BigDecimal.valueOf(string);
        }
    };
}
```

4.7. Serialization

Serialization is the process of transforming an EMF model into its textual representation. Thereby, serialization complements parsing and lexing.

In Xtext, the process of serialization is split into three steps:

1. Matching the model elements with the grammar rules and creating a stream of tokens. This is done by the [Parse Tree Constructor](#).
2. Mixing existing hidden tokens (whitespaces, comments, etc.) into the token stream. This is done by the [Hidden Token Merger](#).
3. Adding needed whitespaces or replacing all whitespaces using a [Formatter](#).

Serialization is invoked when calling [XtextResource](#).`save(...)`. Furthermore, [SerializerUtil](#) provides resource-independent support for serialization.

4.7.1. The Contract

The contract of serialization is that when a model is serialized to its textual representation and then loaded (parsed) again, the loaded model equals the original model. Please be aware that this does *not* imply, that when loading a textual representation and serializing it again that both textual representations equal each other. For example, this is the case when a default value is used in a textual representation and the assignment is optional. Another example is:

```
MyRule:
    (xval+=ID | yval+=INT)*;
```

`MyRule` in this example reads ID- and INT-elements which may occur in an arbitrary order in the textual representation. However, when serializing the model all ID-elements will be written first and then all INT-elements. If the order is important it can be preserved by storing all elements in the same list – which may require wrapping the ID- and INT-elements into objects.

4.7.2. Parse Tree Constructor

The Parse Tree Constructor usually doesn't need to be customized since it is automatically derived from the [Xtext Grammar](#). However, it can be a good idea to look into it to understand its error messages and its runtime performance.

For serialization to succeed, the Parse Tree Constructor must be able to *consume* every element of the to-be-serialized EMF model. To *consume* means, in this context, to write the element to the textual representation of the model. This can turn out to be a not-so-easy-to-fulfill requirement, since a Grammar usually introduces implicit constraints to the Ecore model. Example:

```
MyRule:
    (sval+=ID ival+=INT)*;
```

This example introduces the constraint `sval.size() == ival.size()`. Models which violate this constraint are valid EMF models, but they can not be serialized. To check whether a model complies with

all constraints introduced by the grammar, the only way is currently to invoke the Parse Tree Constructor. If this changes at some day, there will be news in [bugzilla 239565](#).

For the Parse Tree Constructor, this can lead to the scenarios, that

- a model element can not be consumed. This can have the following reasons/solutions:
 - The model element should not be stored in the model.
 - The grammar needs an assignment which would consume the model element.
 - The [Transient Value](#) service could be used to indicate that this models element should not be consumed.
- an assignment in the grammar has no corresponding model element. The Parse Tree Constructor considers a model element not to be present if it is *unset* or equals its default value. However, the parse tree constructor may serialize default values if this is required by a grammar constraint to be able to serialize another model element. The following solution may help to solve such a scenario:
 - A model element should be added to the model.
 - The assignment in the grammar should be made optional.

To understand error messages and performance issues of the Parse Tree Constructor it is important to know that it implements a backtracking approach. This basically means that the grammar is used to specify the structure of a tree in which one path (from the root node to a leaf node) is a valid serialization of a specific model. The Parse Tree Constructor's task is to find this path – with the condition, that all model elements are consumed while walking this path. The Parse Tree Constructor's strategy is to take the most promising branch first (the one that would consume the most model elements). If the branch leads to a dead end (for example, if a model element needs to be consumed that is not present in the model), the Parse Tree Constructor goes back the path until a different branch can be taken. This behavior has two consequences:

- In case of an error, the Parse Tree Constructor has found only dead ends but no leaf. It can not tell which dead end is actually erroneous. Therefore, the error message lists dead ends of the long paths, a fragment of their serialization and the reason why the path could not be continued at this point. The developer has to judge on his own which reason is the actual error.
- For reasons of performance, it is critical that the Parse Tree Constructor takes the right branch first and detects wrong branches early. One way to archive this is to avoid having many rules which return the same type and which are called from within the same grammar-alternative.

4.7.3. Transient Values

Transient Values are values or model elements which are not persisted (written to the textual representation in the serialization phase). If a model contains model elements which can not be serialized with the current grammar, it is critical to mark them transient using the [ITransientValueService](#), or serialization will fail. The default implementation marks all model elements transient, that are *unset* or equal their default value.

4.7.4. Unassigned Text

Unassigned Text are data rule calls or terminal rule calls which do not reside within an association. Example:

```
PluralRule:
  'contents:' count=INT Plural;

terminal Plural:
  'item' | 'items';
```

Valid DSL-Scripts for this example are `contents 1 item` or `contents 5 items`. However, it is not stored in the semantic model whether the keyword `item` or `items` has been parsed. This is due to the fact that the rule call `Plural` is unassigned. However, the [Parse Tree Constructor](#) needs a decision which value to write during serialization. This decision can be made by implementing the [IUnassignedTextSerializer](#).

4.7.5. Cross Reference Serializer

The Cross Reference Serializer specifies which values are to be written to the textual representation for cross references. This behavior can be customized by implementing [ICrossReferenceSerializer](#). The default implementation delegates to [ILinkingService](#), which may be the better place for customization.

4.7.6. Hidden Token Merger

After the [Parse Tree Constructor](#) has done its job to create a stream of tokens which are to be written to the textual representation, the Hidden Token Merger ([IHiddenTokenMerger](#)) mixes existing hidden tokens into this token stream. The default implementation uses the hidden tokens (whitespaces, linebreaks, comments) from the node model. The [IHiddenTokenMerger](#) is the factory for a [Token Stream](#) which is fed by the [Parse Tree Constructor](#) and which writes to another Token Stream.

4.7.7. Token Stream

The [Parse Tree Constructor](#), the [Hidden Token Merger](#) and the [Formatter](#) use [ITokenStream](#) for their output, and the latter two for their input as well. This makes them chainable. Token Streams can be converted to String using the [TokenStringBuffer](#) and to `java.io.OutputStream` using the [TokenOutputStream](#). Maybe there will be an implementation to reconstruct a node model as well at some point in the future. While providing fast output due to the stream pattern, Token Streams allow easy manipulation of the stream, such as mixing in whitespaces or manipulating them.

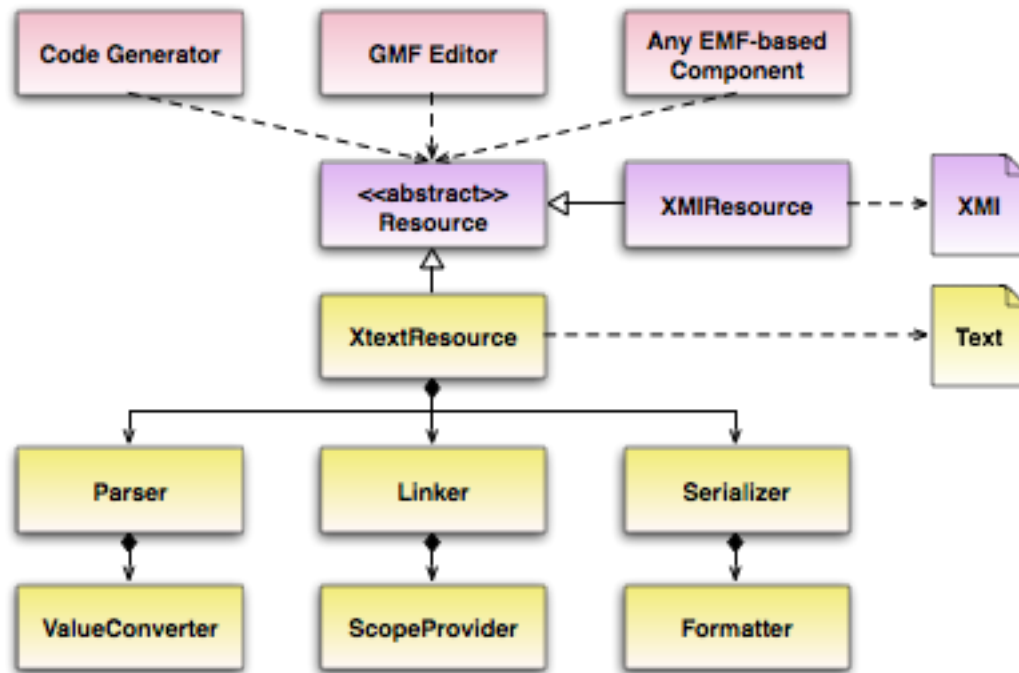

```
public interface ITokenStream {
    public void close() throws IOException;
    public void writeHidden(EObject grammarElement, String value) throws IOException;
    public void writeSemantic(EObject grammarElement, String value) throws IOException;
}
```

4.8. Integration with EMF

Xtext relies heavily on EMF internally, but it can also be used as the serialization backend of other EMF-based tools.

4.8.1. XtextResource Implementation

Xtext provides an implementation of EMF's resource, the [XtextResource](#). This does not only encapsulate the parser that converts text to an EMF model but also the serializer working the opposite direction. That way, an Xtext model just looks like any other Ecore-based model from the outside, making it amenable for the use other EMF based tools. In fact, the Xpand templates in the generator plug-in created by the Xtext wizard do not make any assumption on the fact that the model is described in Xtext, and they would work the same with any model based on the same Ecore model of the language. So in the ideal case, you can switch the serialization format of your models to your self-defined DSL by just replacing the resource implementation used by your other modeling tools.

The generator fragment [ResourceFactoryFragment](#) registers a factory for the [XtextResource](#) to EMF's resource factory registry, such that all tools using the default mechanism to resolve a resource implementation will automatically get that resource implementation.

Using a self-defined textual syntax as the primary storage format has a number of advantages over the default XMI serialization, e.g.

- You can use well-known and easy-to-use tools and techniques for manipulation, such as text editors, regular expressions, or stream editors.
- You can use the same tools for version control as you use for source code. Merging and diffing is performed in a syntax the developer is familiar with.
- It is impossible to break the model such that it cannot be reopened in the editor again.
- Models can be fixed using the same tools, even if they have become incompatible with a new version of the meta model.

Xtext targets easy to use and naturally feeling languages. It focusses on the lexical aspects of a language a bit more than on the semantic ones. As a consequence, a referenced meta model can contain more concepts than are actually covered by the Xtext grammar. As a result, not everything that is possibly expressed in the Ecore-based model can be serialized back into a textual representation with regards to the grammar. So if you want to use Xtext to serialize your models as described above, it is good to have a couple of things in mind:

- Prefer optional rule calls (cardinality ? or *) to mandatory ones (cardinality + or none), such that missing references will not obstruct serialization.
- You should never use an Xtext-Editor on the same model instance as a self-synchronizing other editor, e.g. a canonical GMF editor. The Xtext parser replaces re-parsed subtrees of the AST rather than modifying it, so elements will become stale. Additional information, such as graphical properties in the case of GMF, attached these elements are likely to be lost. As the Xtext editor continuously re-parses the model on changes, this will happen rather often. It is safer to synchronize editors on file changes.
- Implement an [IFragmentProvider](#) to make the XtextResource return stable fragments for its contained elements, e.g. based on composite names rather than order of appearance.

4.8.2. Fragment Provider (referencing Xtext models from other EMF artifacts)

Although inter-Xtext linking is not done by URIs, you may want to be able to reference your `EObject` from non-Xtext models. In those cases URIs are used, which are made up of a part identifying the resource. Each `EObject` contained in a resource can be identified by a so called *fragment*.

A fragment is a part of an EMF URI and needs to be unique per resource.

The generic XMI resource shipped with EMF provides a generic path-like computation of fragments. With an XMI or other binary-like serialization it is also common and possible to use UUIDs.

However with a textual concrete syntax we want to be able to compute fragments out of the given information. We don't want to force people to use UUIDs (i.e. synthetic identifiers) or relative generic paths (very fragile), in order to refer to `EObjects`.

Therefore one can contribute a so called `IFragmentProvider` per language.

```
public interface IFragmentProvider extends ILanguageService {

    /**
     * Computes the local ID of the given object.
     * @param obj
     *      The EObject to compute the fragment for
     * @return the fragment, which can be an arbitrary string but must be
     *         unique within a resource. Return null to use default
     *         implementation
     */
    String getFragment(EObject obj);

    /**
     * Locates an EObject in a resource by its fragment.
     * @param resource
     * @param fragment
     * @return the EObject
     */
    EObject getEObject(Resource resource, String fragment);
}
```

Note that the currently available default fragment provider does nothing (i.e. refers to the default behavior of EMF).

Chapter 5. IDE concepts

For the following part we will refer to a concrete example grammar in order to explain certain aspect of the UI more clearly. The used example grammar is as follows:

```
grammar org.eclipse.text.documentation.Sample
    with org.eclipse.xtext.common.Terminals

generate gen 'http://www.eclipse.org/xtext/documentation/Sample' as gen

Model :
    "model" intAttribute=INT (stringDescription=STRING)? "{"
        (rules += AbstractRule)*
    "}"
;

AbstractRule:
    RuleA | RuleB
;

RuleA :
    "RuleA" "(" name = ID ")" ;

RuleB return gen::CustomType:
    "RuleB" "(" ruleA = [RuleA] ")" ;
```

5.1. Managing Concurrency

text

5.2. Label Provider

A nice part of the Eclipse tooling that comes with Xtext is the outline view. It shows the structure of your model as a tree and allows quick navigation to model elements. Thus it helps to get an overview on the current state in the editor at a glance. To make the appearance of the outline more appealing it is very easy possible to provide customization for the label and the image that is used for an element. Actually this customization will be used at various places in your IDE, for example in the window that displays completion proposals when content assist was invoked. (Customizing the structure of the outline is described in a separate [chapter](#)).

The `LabelProvider` is the service which is used to compute the image for model elements of – as its name suggests – the label that represents an element. What you basically have to do is to provide an implementation for two methods which read `Image getImage(Object)` and `String getText(Object)` respectively. As this tends to be cumbersome due to `instanceof` and cast orgies, Xtext ships with a reasonable and convenient default implementation.

5.2.1. DefaultLabelProvider

The default implementation of the `LabelProvider` interface utilizes the polymorphic dispatcher idiom to implement an external visitor as the requirements of the `LabelProvider` are kind of a best match for this pattern. It comes down to the fact that the only thing you need to do is to implement a method that matches a specific signature. It either provides a image filename or the text to be used to represent your model element. Have a look at following example to get a more detailed idea about the `DefaultLabelProvider`.

```

public class SampleLabelProvider extends DefaultLabelProvider {

    String text(RuleA rule) {
        return "Rule: " + rule.getName();
    }

    String image(RuleA rule) {
        return "ruleA.gif";
    }

    String image(RuleB rule) {
        return "ruleB.gif";
    }

}

```

The declarative implementation of the label itself is pretty straightforward. The image in turn is expected to be found in a resource named `icons/<result of image-method>` in your plugin. This path is actually configurable by google guice. Have a look at the [PluginImageHelper](#) to learn about the customizing possibilities.

What's especially nice about the default implementation is the actual reason for its class name: It provides very reasonable defaults. To compute the label for a certain model element, it will at first have a look for a `EAttribute` that's called `name` and try to use this one. If it cannot find a feature like this, it will try to use the first feature, that can be used best as a label. At worst it will return the class name of the model element, which is kind of unlikely to happen.

More advanced usage patterns of the `DefaultLabelProvider` include a dispatching to an error handler called `String error_text(Object, Exception)` and `String error_image(Object, Exception)` respectively.

5.3. Content Assist

The Xtext generator, amongst other things, generates the following two content assist (CA) related artifacts:

- an abstract proposal provider class named `'Abstract[Language]ProposalProvider'` generated into the `src-gen` folder within the `ui` project
- a concrete descendent in the `src`-folder of the `ui` project `ProposalProvider`

First we will investigate the generated `Abstract[Language]ProposalProvider` with methods that look like this:

5.3.1. ProposalProvider

```

public void complete[TypeName]_[FeatureName](
    EObject model,
    Assignment assignment,
    ContentAssistContext context,
    ICompletionProposalAcceptor acceptor) {
    // clients may override
}

public void complete_[RuleName](
    EObject model,
    RuleCall ruleCall,
    ContentAssistContext context,
    ICompletionProposalAcceptor acceptor) {
    // clients may override
}

```

The snippet above indicates that the generated `ProposalProvider` class contains a `complete*`-method for each assigned feature in the grammar and for each rule. The brackets are placeholders that should give

a clue about the naming scheme, that is used to create the various entry points for clients. The generated proposal provider falls back to some default behavior for cross references. Furthermore it inherits the logic that was introduced in reused grammars.

Clients who want to customize the behavior may override the methods from the `AbstractProposalProvider` or in turn introduce new methods with specialized parameters. The framework dispatches method calls according to the current context to the most concrete implementation, that can be found.

It is important to know, that for a given offset in a model file, many possible grammar elements exist. The framework dispatches to the method declarations for any valid element. That means, that a bunch of "complete.*" may be called.

5.3.2. Sample Implementation

To provide a dummy proposal for the description of a model object, you may introduce a specialization of the generated method and implement it as follows. This will give 'Description for model #7' for a model with the `intAttribute '7'`

```
public void completeModel_StringDescription (
    Model model,
    Assignment assignment,
    ContentAssistContext context,
    ICompletionProposalAcceptor acceptor) {
    // call implementation in superclass
    super.completeModel_StringDescription(
        model,
        assignment,
        context,
        acceptor);

    // compute the plain proposal
    String proposal = "Description for model #" + model.getIntAttribute();

    // convert it to a valid STRING-terminal
    proposal = getValueConverter().toString(proposal, "STRING");

    // create the completion proposal
    // the result may be null as the createCompletionProposal(..) methods
    // check for valid prefixes
    // and terminal token conflicts
    ICompletionProposal completionProposal =
        createCompletionProposal(proposal, context);

    // register the proposal, the acceptor handles null-values gracefully
    acceptor.accept(completionProposal);
}
```

5.4. Template Proposals

Xtext-based editors automatically support code templates. That means that you get the corresponding preference page where users can add and change template proposals. If you want to ship a couple of default templates, you have to put a file named

`templates.xml`

inside the `templates` directory of the generated ui-plugin. This file contains templates in a format as described in [eclipse help](#).

By default Xtext registers ContextTypes for each Rule (`.[RuleName]`) and for each keyword (`.kw_[keyword]`), as long as the keywords are valid identifiers. If you don't like these defaults you'll have to subclass `org.eclipse.xtext.ui.common.editor.templates.XtextTemplateContextTypeRegistry` and configure it via Guice.

In addition to the standard Template proposal extension mechanism, Xtext ships with a predefined set of TemplateVariableResolver to resolve special variable types inside a given template (i.e. TemplateContext). Besides the standard template variables available in `org.eclipse.jface.text.templates.GlobalTemplateVariables` like `${user}`, `${date}`, `${time}`, `${cursor}`, etc., these TemplateVariableResolver support the automatic resolving of CrossReferences (type `CrossReferences`) and Enumerations (type `Enum`) like it is explained in the following sections.

5.4.1. CrossReference TemplateVariableResolver

Xtext comes with a specific template variable resolver (`org.eclipse.jface.text.templates.TemplateVariableResolver`) called `CrossReferenceResolver`, which can be used to place cross refs within a template.

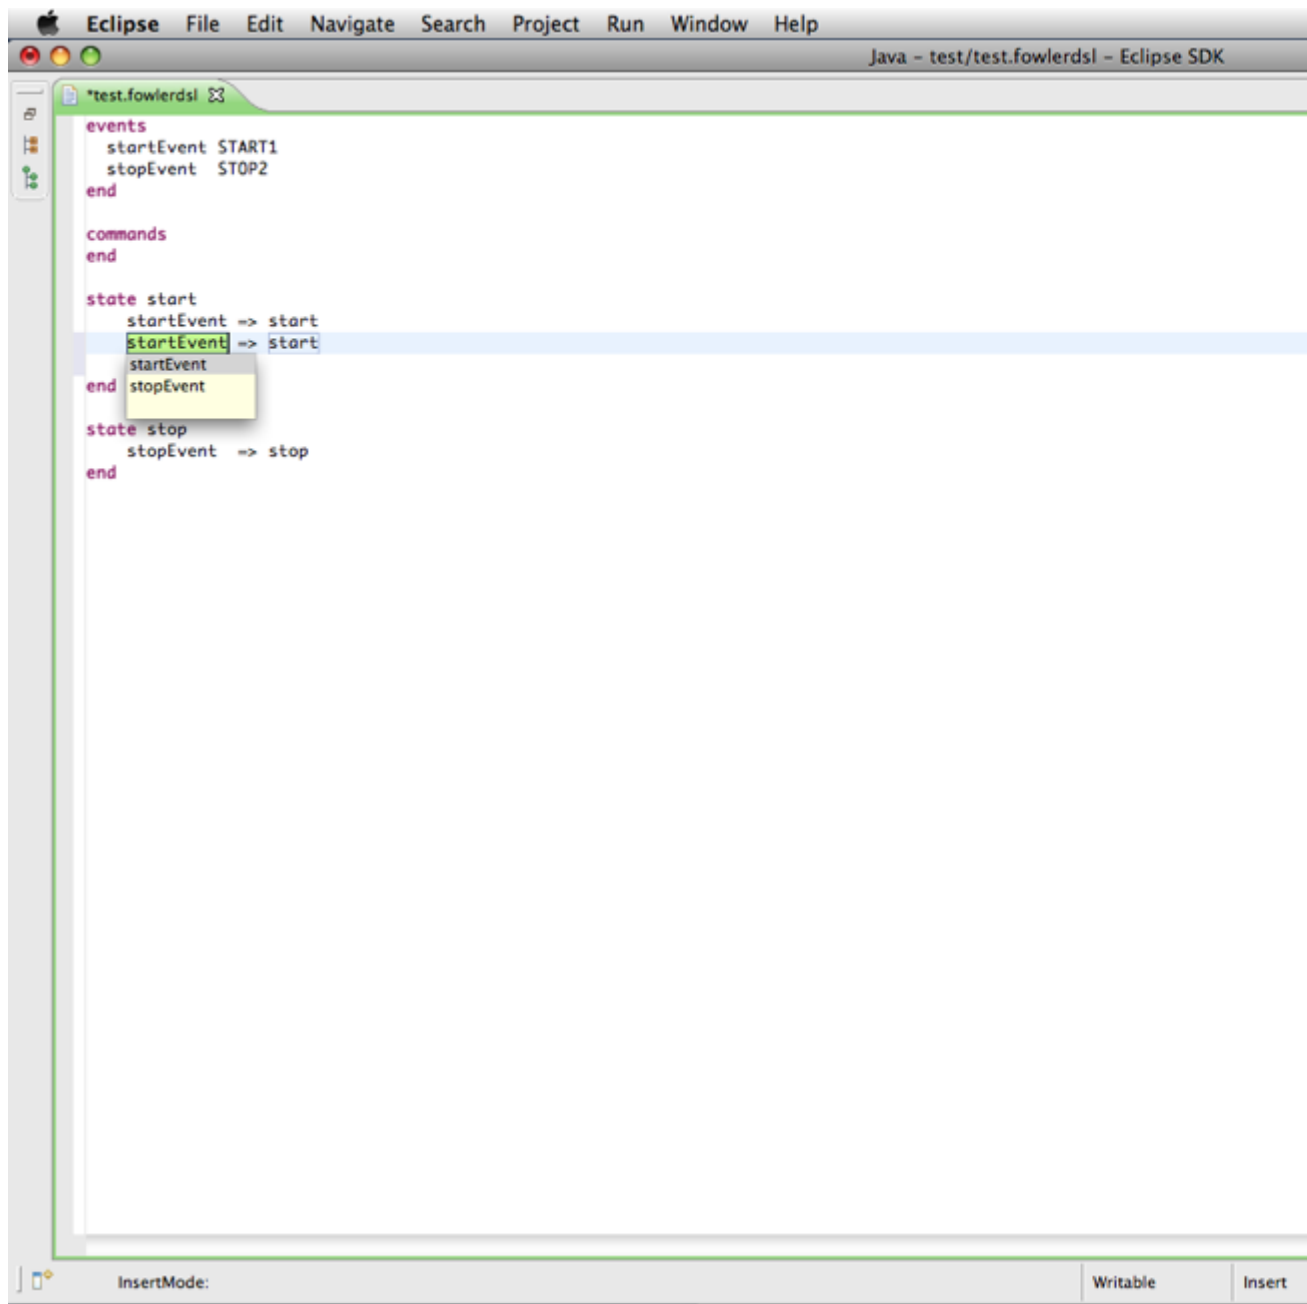

The syntax is as follows:

```
${displayText:CrossReference('MyType.myRef')}
```

For example the following template:

```
<template name="transition" description="event transition" id="transition"
  context="org.eclipse.xtext.example.FowlerDsl.Transition" enabled="true">
  ${event:CrossReference('Transition.event')} => ${state:CrossReference('Transition.state')}
</template>
```

yields the text `event => state` and allows selecting any events and states using a drop down.

5.4.2. Enumeration TemplateVariableResolver

The

`org.eclipse.xtext.ui.common.editor.templates.EnumTemplateVariableResolver` resolves a template variable to `EEnumLiteral` literals which are assignment-compatible to the enumeration type declared as the first parameter of the the

`Enum`

`TemplateVariable`.

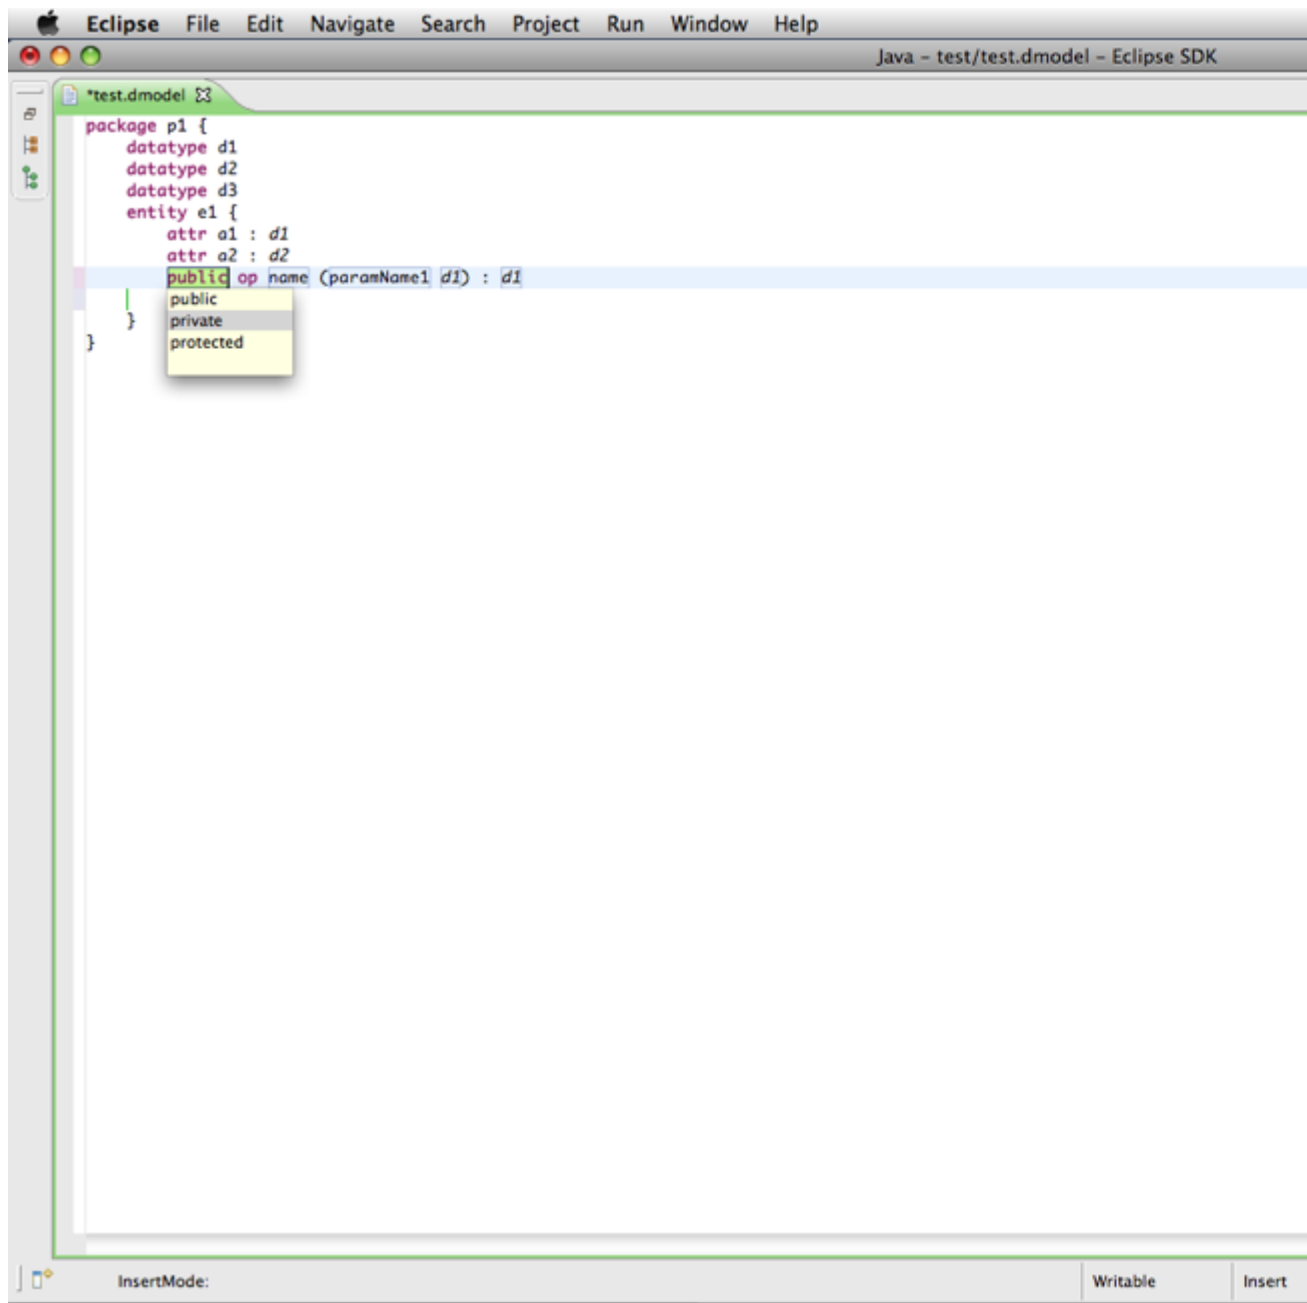

The syntax is as follows:

```
${displayText:Enum('Visibility')}
```

For example the following template (taken from the domainmodel example):

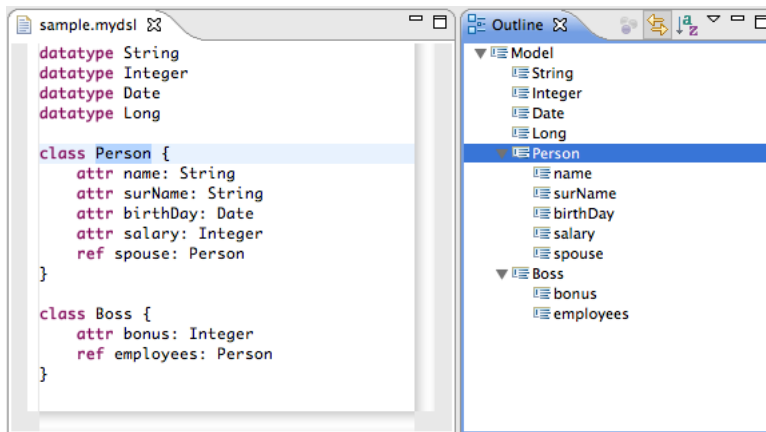

```
<template name="Operation" description="template for an Operation"
  id="org.eclipse.xtext.example.Domainmodel.Operation"
  context="org.eclipse.xtext.example.Domainmodel.Operation" enabled="true">
  ${visibility:Enum('Visibility')} op ${name}
</template>
```

yields the text `visibility op name` where the display text `'visibility'` is replaced with a drop down filled with the literal values as defined in the `Visibility EEnumeration`.

5.5. Outline View

Xtext provides an outline view to help you navigate your models. By default, it provides a hierarchical view on your model and allows you to sort tree elements alphabetically. Selecting an element in the outline will highlight the corresponding element in the text editor. Users can choose to synchronize the outline with the editor selection by clicking the *Link with Editor* button.

You can customize various aspects of the outline by providing implementation for its various interfaces. The following sections show how to do this.

5.5.1. Influencing the outline structure

In its default implementation, the outline view shows the containment hierarchy of your model. This should be sufficient in most cases. If you want to adjust the structure of the outline, i.e., by omitting a certain kind of node or by introducing additional (artificial / virtual) nodes, you customize the outline by implementing [ISemanticModelTransformer](#).

The Xtext wizard creates an empty transformer class (`MyDslTransformer`) for your convenience. To transform the semantic model delivered by the Xtext parser, you need to provide transformation methods for each of the meta classes that are of interest:

```

public class MyDslTransformer extends
    AbstractDeclarativeSemanticModelTransformer {
    /**
     * This method will be called by naming convention:
     * - method name must be createNode
     * - first param: subclass of EObject
     * - second param: ContentOutlineNode
     */
    public ContentOutlineNode createNode(
        Attribute semanticNode, ContentOutlineNode parentNode) {
        ContentOutlineNode node = super.newOutlineNode(semanticNode, parentNode);
        node.setLabel("special " + node.getLabel());
        return node;
    }

    public ContentOutlineNode createNode(
        Property semanticNode, ContentOutlineNode parentNode) {
        ContentOutlineNode node = super.newOutlineNode(semanticNode, parentNode);
        node.setLabel("pimped " + node.getLabel());
        return node;
    }

    /**
     * This method will be called by naming convention:
     * - method name must be getChildren
     * - first param: subclass of EObject
     */
    public List<EObject> getChildren(Attribute attribute) {
        return attribute.eContents();
    }

    public List<EObject> getChildren(Property property) {
        return NO_CHILDREN;
    }
}

```

To make sure Xtext picks up your new outline transformer, you have to register your implementation with your UI module:

```

public class MyDslUiModule extends AbstractXtextUiModule {

    @Override
    public Class<? extends ISemanticModelTransformer> bindISemanticModelTransformer() {
        return MyDslTransformer.class;
    }
    ...
}

```

5.5.2. Filtering

Often, you want to allow users to filter the contents of the outline to make it easier to concentrate on the relevant aspects of the model. To add filtering capabilities to your outline, you need to add [AbstractFilterActions](#) to the outline. Actions can be contributed by implementing and registering a [DeclarativeActionBarContributor](#).

To register a DeclarativeActionBarContributor, add the following lines to your MyDslUiModule class:

```

/**
 * Use this class to register components to be used within the IDE.
 */
public class MyDslUiModule extends org.xtext.example.AbstractMyDslUiModule {

    ...

    @Override
    public Class<? extends IActionBarContributor> bindIActionBarContributor() {
        return MyDslActionBarContributor.class;
    }
}

```

The action bar contributor will look like this:

```

public class MyDslActionBarContributor extends
    DeclarativeActionBarContributor {
    public Action addFilterParserRulesToolbarAction(
        XtextContentOutlinePage page) {
        return new FilterFooAction(page);
    }
}

```

Filter actions must extend `AbstractFilterAction` (this ensures that the action toggle state is handled correctly):

```

import org.eclipse.jface.viewers.ViewerFilter;
import org.eclipse.xtext.ui.common.editor.outline.XtextContentOutlinePage;
import
    org.eclipse.xtext.ui.common.editor.outline.actions.AbstractFilterAction;
import org.eclipse.xtext.xtext.ui.Activator;

public class FilterFooAction extends AbstractFilterAction {

    public FilterFooAction(XtextContentOutlinePage outlinePage) {
        super("Filter Foo", outlinePage);
        setToolTipText("Show / hide foo");
        setDescription("Show / hide foo");
        setImageDescriptor(Activator.getImageDescriptor("icons/foo.gif"));
        setDisabledImageDescriptor(Activator.getImageDescriptor("icons/foo.gif"));
    }

    @Override
    protected String getToggleId() {
        return "FilterFooAction.isChecked";
    }

    @Override
    protected ViewerFilter createFilter() {
        return new FooOutlineFilter();
    }
}

```

The filtering itself will be performed by `FooOutlineFilter`:

```

import org.eclipse.emf.ecore.EClass;
import org.eclipse.jface.viewers.Viewer;
import org.eclipse.jface.viewers.ViewerFilter;
import org.eclipse.xtext.XtextPackage;
import org.eclipse.xtext.ui.common.editor.outline.ContentOutlineNode;

public class FooOutlineFilter extends ViewerFilter {

    @Override
    public boolean select(
        Viewer viewer, Object parentElement, Object element) {
        if ((parentElement != null)
            && (parentElement instanceof ContentOutlineNode)) {
            ContentOutlineNode parentNode = (ContentOutlineNode) parentElement;
            EClass clazz = parentNode.getClass();
            if (clazz.equals(MyDslPackage.Literals.ATTRIBUTE)) {
                return false;
            }
        }
        return true;
    }
}

```

5.5.3. Context menus

You might want to register context menu actions for specific elements in the outline, e.g. to allow users of your DSL to invoke a generator or to validate the selected element. As all elements in the outline are [ContentOutlineNodes](#), you cannot easily register an [Object contribution](#). (Besides, using the extension point `org.eclipse.ui.popupMenus` is regarded somewhat old school – you should rather use the new command and expression framework, as depicted below).

So to register context menus for specific node types of your meta model, you need to do the following:

- register a [IContentOutlineNodeAdapterFactory](#) which will translate [ContentOutlineNodes](#) to their underlying node type
- register a menu contribution to add a command / handler pair to the context menu for the specific node types you're interested in.

5.5.3.1. Registering an IContentOutlineNodeAdapterFactory

Create a subclass of [DefaultContentOutlineNodeAdapterFactory](#) - this class contains some base infrastructure to manage adapters for your node types. In your subclass, you need to override `getAdapterList()` and return an array of classes. This is the list of classes you want to add context menus to:

```

public class MyDslContentOutlineNodeAdapterFactory extends
    DefaultContentOutlineNodeAdapterFactory {
    @SuppressWarnings("unchecked")
    private static final Class[] types = { Attribute.class };

    @SuppressWarnings("unchecked")
    public Class[] getAdapterList() {
        return types;
    }
}

```

Register this class with your `MyDslUiModule` to make it available to your DSL editor:

```
public class MyDslUiModule extends AbstractMyDslUiModule {
    ...
    public Class<? extends IContentOutlineNodeAdapterFactory>
        bindIContentOutlineNodeAdapterFactory() {
        return org.example.myDSLContentOutlineNodeAdapterFactory.class;
    }
    ...
}
```

5.5.3.2. Registering a menu contribution

After you have registered the [IContentOutlineNodeAdapterFactory](#), you can add command / handler pairs to the context menu.

First, you need to define a command – it will serve as a handle to glue together the handler and the menu contribution:

```
<extension
  point="org.eclipse.ui.commands">
  <command
    id="org.example.mydsl.ui.editor.outline.SampleOutlineCommand"
    name="Sample Command"
    description="Just a sample command">
  </command>
</extension>
```

Next, you need to define a handler which will eventually execute the code to operate on the selected node. Please pay special attention to the attribute `commandId` - it must match the `id` attribute of your command.

```
<extension
  point="org.eclipse.ui.handlers">
  <handler
    class="org.example.mydsl.ui.editor.outline.SampleOutlineNodeHandler"
    commandId="org.example.mydsl.ui.editor.outline.SampleOutlineCommand">
  </handler>
</extension>
```

Finally, define a [menuContribution](#) to add the command to the context menu:

```
<extension
  point="org.eclipse.ui.menus">
  <menuContribution
    locationURI="popup:org.eclipse.xtext.ui.common.outline?after=additions">
    <command
      commandId="org.example.mydsl.ui.editor.outline.SampleOutlineCommand"
      label="Sample action registered for Attributes">
      <visibleWhen checkEnabled="false">
        <iterate>
          <adapt type="org.example.mydsl.Attribute" />
        </iterate>
      </visibleWhen>
    </command>
  </menuContribution>
</extension>
```

Again, pay attention to the `commandId` attribute. The connection between your node type(s) and the menu contribution is made by the part `<adapt type="org.example.mydsl.Attribute" />`.

5.6. Navigation and Hyperlinking

text

5.7. Formatting (Pretty Printing)

A formatter can be implemented via the [IFormatter](#) service. Technically speaking, a formatter is a [Token Stream](#) which inserts/removes/modifies hidden tokens (whitespaces, linebreaks, comments).

The formatter is invoked during the [serialization phase](#) and when the user triggers formatting in the editor (for example, using the CTRL+SHIFT+F shortcut).

Xtext ships with two formatters:

- The [OneWhitespaceFormatter](#) simply writes one whitespace between all tokens.
- The [AbstractDeclarativeFormatter](#) allows advanced configuration using a [FormattingConfig](#). Both are explained in the [next chapter](#).

5.7.1. Declarative Formatter

A declarative formatter can be implemented by sub-classing `{org.eclipse.xtext/src/org.eclipse.xtext.formatting.impl.AbstractDeclarativeFormatter}`, as shown in the following example:

```
public class ExampleFormatter extends AbstractDeclarativeFormatter {

    @Override
    protected void configureFormatting(FormattingConfig c) {
        ExampleLanguageGrammarAccess f = (ExampleLanguageGrammarAccess) getGrammarAccess();

        c.setAutoLinewrap(120);

        // Line
        c.setLinewrap(2).after(f.getLineAccess().getSemicolonKeyword_1());
        c.setNoSpace().before(f.getLineAccess().getSemicolonKeyword_1());

        // TestIndentation
        c.setIndentation(f.getTestIndentationAccess().getLeftCurlyBracketKeyword_1(),
            f.getTestIndentationAccess().getRightCurlyBracketKeyword_3());
        c.setLinewrap().after(f.getTestIndentationAccess().getLeftCurlyBracketKeyword_1());
        c.setLinewrap().after(f.getTestIndentationAccess().getRightCurlyBracketKeyword_3());

        // Param
        c.setNoLinewrap().around(f.getParamAccess().getColonKeyword_1());
        c.setNoSpace().around(f.getParamAccess().getColonKeyword_1());

        // comments
        c.setNoLinewrap().before(f.getSL_COMMENTRule());
    }
}
```

The formatter has to implement the method `configureFormatting(...)` which is supposed to declaratively set up a [FormattingConfig](#).

The [FormattingConfig](#) consist general settings and a set of rules:

5.7.1.1. General FormattingConfig Settings

- `setAutoLinewrap(int)` defines the amount of characters after which a linebreak should be dynamically inserted between two tokens. The rule `setNoLinewrap()` can be used to suppress this behavior locally. The default is 80.
- `setIndentationSpace(String)` defines the string which is used for a single degree of indentation. The default is two whitespaces.

- `setWhitespaceRule(AbstractRule)` defines the grammar rule which is used to match whitespaces. This is needed by the formatter to identify whitespaces and to insert whitespaces. The default is the rule named `WS`.
- `setIndentation(startele, endele)` increases the level of indentation when `startele` is matched and decreases the level when `endele` is matched. The matching of elements happens in the same way as it does for formatting rules.

5.7.1.2. FormattingConfig Rules

Per default, the [Declarative Formatter](#) inserts one whitespace between two tokens. Rules can be used to specify a different behavior. They consist of two parts: *When* to apply the rule and *what* to do.

To understand *when* a rule is applied think of a stream of tokens whereas each token is associated with the corresponding grammar element. The rules are matched against these grammar elements. The following matching constructs exist.

- `after(ele)`: The rule is executed after the grammar element `ele` has been matched. For example, if your grammar uses the keyword “;” to end lines, this can instruct the formatter to insert a linebreak after the semicolon.
- `before(ele)`: The rule is executed before the matched element. For example, if your grammar contains lists which separate its values with keyword “,”, you this can instruct the formatter to suppress the whitespace before the comma.
- `around(ele)`: This is the same as `before(ele)` combined with `after(ele)`.
- `between(ele1, ele2)`: This matches if `ele2` directly follows `ele1`. There may be no other elements in between.
- `bounds(ele1, ele2)`: This is the same as `before(ele1)` combined with `after(ele2)`.
- `range(ele1, ele2)`: The rule is enabled when `ele1` is matched, and disabled when `ele2` is matched. Thereby, the rule is active for the complete region which is surrounded by `ele1` and `ele2`.

The parameter `ele` can be a grammar’s `AbstractElement` or a grammar’s `AbstractRule`. However, only elements which represent a token in the textual representation can be matched. This are:

- Terminal rules for comments.
- Keywords, Associations, Terminal RuleCalls, Datatype RuleCalls.

After having explained how rules can be activated, this is what they can do:

- `setLinewrap()`: Inserts a linebreak at this position.
- `setLinewrap(int)`: Inserts the specified number of linebreak at this position.
- `setNoLinewrap()`: Suppresses automatic line wrap, which may occur when the line’s length exceeds the defined limit.
- `setNoSpace()`: Suppresses the whitespace between tokens at this position. Be aware that between some tokens a whitespace is required to maintain a valid concrete syntax.

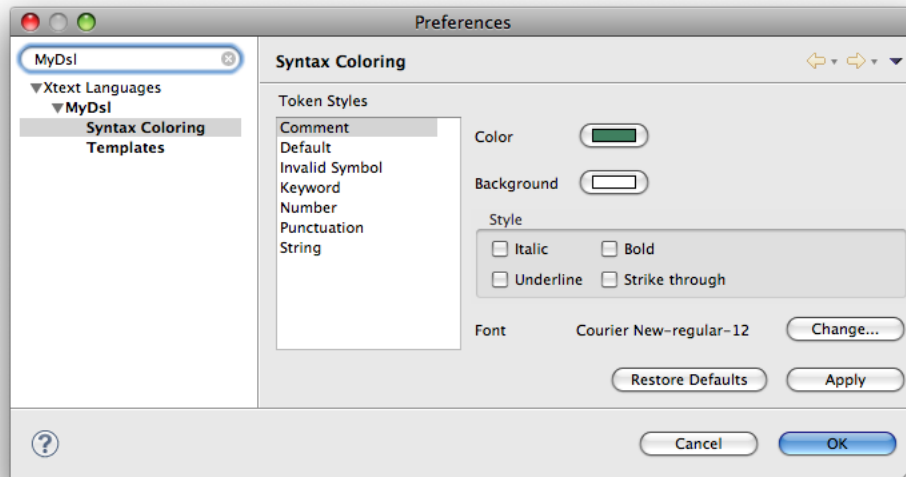

5.8. Syntax Coloring

Besides the already mentioned advanced features like content assist and code formatting the powerful editor for your DSL is capable to mark-up your model-code to improve the overall readability. It is possible to use different colors and fonts according to the meaning of the different parts of your input file. One may want to use some decent colors for large blocks of comment while identifiers, keywords and strings should be colored differently to make it easier to distinguish between them. This kind of text decorating mark-up does not influence the semantics of the various sections but helps to understand the meaning and to find errors in the source code.

```
entity Person {  
    // line comment  
    property Name : String  
    "unexpected string"  
}
```

The highlighting is done in two stages. This allows for sophisticated algorithms that are executed asynchronously to provide advanced coloring while simple pattern matching may be used to highlight parts of the text instantaneously. The latter is called lexical highlighting while the first is based on the meaning of your different model elements and therefore called semantic highlighting.

When you introduce new highlighting styles, the preference page for your DSL is automatically configured and allows the customization of any registered highlighting setting. They are automatically persisted and reloaded on startup.

5.8.1. Lexical Highlighting

The lexical highlighting can be customized by providing implementations of the interface [ILexicalHighlightingConfiguration](#) and the abstract class [AbstractTokenScanner](#). The latter fulfills the interface `ITokenScanner` from the underlying JFace Framework, which may be implemented by clients directly.

The `ILexicalHighlightingConfiguration` is used to register any default style without a specific binding to a pattern in the model file. It is used to populate the preferences page and to initialize the `ITextAttributeProvider`, which in turn is the component that is used to obtain the actual settings for a style's id. An implementation will usually be very similar to the [DefaultLexicalHighlightingConfiguration](#) and read like this:

```

public class DefaultLexicalHighlightingConfiguration
    implements ILexicalHighlightingConfiguration {

    public static final String KEYWORD_ID = "keyword";
    public static final String COMMENT_ID = "comment";

    public void configure(IHighlightingConfigurationAcceptor acceptor) {
        acceptor.acceptDefaultHighlighting(KEYWORD_ID, "Keyword", keywordTextStyle());
        acceptor.acceptDefaultHighlighting(COMMENT_ID, "Comment", // ...
        // ...
    }

    public TextStyle keywordTextStyle() {
        TextStyle textStyle = new TextStyle();
        textStyle.setColor(new RGB(127, 0, 85));
        textStyle.setStyle(SWT.BOLD);
        return textStyle;
    }

    // ...
}

```

Implementations of the `ITokenScanner` are responsible for splitting the content of a document into various parts, the so called tokens, and return the highlighting information for each identified range. It is critical that this is done very efficiently because this component is used on each keystroke. Xtext ships with a default implementation that is based on the lexer that is generated by ANTLR which is very lightweight and fast. This default implementation can be customized by clients very easily. They simply have to bind another implementation of the [AbstractAntlrTokenToAttributeIdMapper](#). To get an idea about it, have a look at the [DefaultAntlrTokenToAttributeIdMapper](#).

5.8.2. Semantic Highlighting

The semantic highlighting stage is executed asynchronously in the background and can be used to calculate highlighting states based on the meaning of the different model elements. Users of the editor will notice a very short delay after they have edited the text until the styles are actually applied to the document. This keeps the editor responsive while providing aid when reading and writing your model.

As for the lexical highlighting there exist two interfaces whose implementations work closely together and allow the customization of the semantic highlighting. Namely these are the [ISemanticHighlightingConfiguration](#) and [ISemanticHighlightingCalculator](#). While the configuration for the semantic highlighting works the same way as the `ILexicalHighlightingConfiguration`, the `ISemanticHighlightingCalculator` is the primary hook to implement the logic that will compute ranges based on the model elements.

The framework will pass the `XtextResource` and an [IHighlightedPositionAcceptor](#) to the calculator. It is ensured, that the resource will not be altered externally until the called method `provideHighlightingsFor` returns. The task is to navigate your semantic model and compute various ranges based on the node information and associate styles with them. This may read similar to the following snippet:

```

public void provideHighlightingFor(XtextResource resource,
    IHighlightedPositionAcceptor acceptor) {
    if (resource == null)
        return;

    Iterable<AbstractNode> allNodes = NodeUtil.getAllContents(
        resource.getParseResult().getRootNode());
    for (AbstractNode abstractNode : allNodes) {
        if (abstractNode.getGrammarElement() instanceof CrossReference) {
            acceptor.addPosition(node.getOffset(), node.getLength(),
                SemanticHighlightingConfiguration.CROSS_REF);
        }
    }
}

```

This example refers to an implementation of the `ISemanticHighlightingConfiguration` that registers a style for a cross reference. It is pretty much the same implementation as for the previously mentioned sample of an `ILexicalHighlightingConfiguration`.

```

public class SemanticHighlightingConfiguration
    implements ISemanticHighlightingConfiguration {

    public final static String CROSS_REF = "CrossReference";

    public void configure(IHighlightingConfigurationAcceptor acceptor) {
        acceptor.acceptDefaultHighlighting(CROSS_REF,
            "Cross References", crossReferenceTextStyle());
    }

    public TextStyle crossReferenceTextStyle() {
        TextStyle textStyle = new TextStyle();
        textStyle.setStyle(SWT.ITALIC);
        return textStyle;
    }
}

```

The implementor of an `ISemanticHighlightingCalculator` should be aware of performance to ensure a good user experience. It is probably not a good idea to traverse everything of your model when you will only register a few highlighted ranges that can be found easier with some typed method calls. It is strongly advised to use purposeful ways to navigate your model. The parts of Xtext's core that are responsible for the semantic highlighting are pretty optimized in this regard as well. The framework will only update the ranges that actually have been altered, for example. This optimizes the redraw process. It will even move, shrink or enlarge previously announced regions based on a best guess before the next semantic highlighting pass has been triggered after the user has changed the document.

Chapter 6. From oAW to TMF

TMF Xtext is a complete rewrite of the Xtext framework previously released with openArchitectureWare 4.3.1 (oAW). We refer to the version from oAW as oAW Xtext whereas the current Xtext version that is hosted at Eclipse.org will be called TMF Xtext to avoid confusion. oAW Xtext has been around for about 2 years before TMF Xtext was released in June 2009 and has been used by many people to develop little languages and corresponding Eclipse-based IDE support.

TMF Xtext has been improved in many aspects compared to the former version. While it integrates far better into EMF, it offers new fundamental features as well. The overhauled architecture leads to better performance when working with large models and since the whole framework is wired via dependency injection it is highly customizable. Last not least a test coverage of more than 2.000 unit tests provide confidence in the overall quality of TMF Xtext. We have been using the framework in production environments since one of the earlier milestones.

In this document we want to share the experience we made when migrating existing Xtext projects. The document describes the differences between oAW Xtext and TMF Xtext and is intended to be used as a guide to migrate from oAW Xtext to TMF Xtext. For people already familiar with the concepts of oAW Xtext it should also serve as a shortcut to learn TMF Xtext.

6.1. Why a rewrite?

The first thing you might wonder about is why we decided to reimplement the framework from scratch as opposed to use the existing code base and enhance it further on. We decided so because we had learned a lot of lessons from oAW Xtext. Although we wanted to stick with many proven concepts we found the implementation was lacking a solid foundation (the author of these lines is the original author of that non-solid code btw. :-)). The first version of oAW Xtext was basically a proof of concept which was so well received that it had been extended with all kinds of features (some were good, some were bad). Unfortunately code quality, clean and orthogonal concepts and test coverage did not receive the necessary focus.

In addition to this aspects of quality, oAW Xtext suffers from some severe performance problems. The extensive and naive use of Xtend (see next section) prevented many users to use oAW Xtext for growing real-world models.

6.2. Migration overview

Although a couple of things have changed we tried to keep good ideas and left many things unchanged. At the same time we wanted to clean up poor concepts and solve the main problems we and you had with oAW Xtext. From a bird's eye view if you want to migrate an existing oAW Xtext project to TMF Xtext, you mainly just need to rename the old grammar from *.txt to *.xtext and add two lines to the beginning of that document (see below for details). You might also have to change a few keywords, but all in all this is pretty easy and we've migrated a couple of oAW Xtext projects this way without problems. The other aspect where lots of code might have been written for is validation. In oAW Xtext we used Xpand's Check language to define constraints on the meta model. Even though this has been one major reason for the lack of scalability in Xtext we decided to keep the Check language as an option for compatibility reasons (see [Differences in Validation](#)). Therefore, you do not need to translate your existing checks to a different language. Even better, you can overcome some performance issues by leveraging the newly introduced hooks to control the time of validation (while you type, on save, or on triggering an explicit action). Anyway, if you want to provide a slick user experience validation should run fast while you type. Therefore, we strongly encourage you to implement validation using our declarative Java approach (TODO: ref).

We've developed and reviewed a lot of oAW Xtext projects and saw that most of the work was done in the grammar and in the validation view point. Other aspects such as outline view, label provider or content assist have been customized too, but they usually do not contain complicated Xtend code. In some projects the exception was linking and content assist which in oAW Xtext usually forces one to write a lot of duplicated code. While working on this we came up with a new concept called "scopes" that not only streamlines implementation in terms of redundancy. Scopes also increase the overall performance of Xtext. But since the concept of scopes was not carved out in oAW Xtext one usually implemented

a cluttered and duplicated poor copy through linking and content assist. For obvious reasons, we didn't manage to come up with a good compatibility layer. So this is where most of the migration effort will go into if implemented customized linking. But we think the notion of scopes is such a valuable addition that it is worth the refactoring. Also, when looking at existing oAW Xtext projects we found that most projects either didn't change the default linking that much or they came up with their own linking framework anyway.

However, if we have completely misunderstood the situation and your oAW Xtext project cannot be migrated in a reasonable amount of time, please tell us. We want to help you!

6.3. Where are the Xtend-based APIs?

One of the nice things with oAW Xtext was the use of Xtend to allow customizing different aspects of the generated language infrastructure. Xtend is a part of the template language Xpand, which is shipped with oAW (and now is included in M2T Xpand). It provides a nicer expression syntax than Java. Especially the existence of higher-order functions for collections is extremely handy when working with models. In addition to the nice syntax, it provides dynamic polymorphic dispatch, which means that declaring e.g. label computation for a meta model is very convenient and type safe at the same time. In Java one usually has to write `instanceof` and `cast` orgies.

6.3.1. Xtend is hard to debug

While the aforementioned features allow the convenient specification of label and icon providers, outline views, content assist and linking, Xtend is interpreted and therefore hard to debug. Because of that Xpand is shipped with a special debugger facility. Unfortunately, this debugger cannot be used in the context of Xtext since it implies that the Xtend functions have to be called from a workflow. This is not and cannot be the case for Xtext Editors. As a result one has to debug his way through the interpreter, which is hard and inconvenient (even for us, who have written that interpreter).

6.3.2. Xtend is slow

But the problematic debugging in the context of Xtext was not the main reason why there are no Xtend-based APIs beside Check in TMF Xtext. The main reason is that Xtend is too slow to be evaluated "inside" the editor again and again while you type. While Xtend's performance is sufficient when run in a code generator, it is just too slow to be executed on keystroke (or 500ms after the last keystroke, which is when the reconciler reparses, links and validates the model). Xtend is relatively slow, because it supports polymorphic dispatch (the cool feature mentioned above), which means that for each invocation it matches at runtime which function is the best match and it has to do so on each call. Also Xtend supports a pluggable typesystem, where you can adapt to other existing type systems such as JavaBeans or Ecore. This is very powerful and flexible but introduces another indirection layer. Last but not least the code is interpreted and not compiled. The price we pay for all these nice features is reduced performance.

In addition to these scalability problems we have designed some core APIs (e.g. scopes) around the idea of Iterables, which allows for lazy resolution of elements. As Xtend does not know the concept of Iterators you would have to work with lists all the time. Copying collections over and over again is far more expensive than chaining Iterables through filters and transformers like we do with Google Collections in TMF Xtext.

6.3.3. Convenient Java

To summarize the dilemma we had to find a way to allow for convenient, scalable and debuggable APIs. Ultimately we wanted to provide neat DSLs for every view point, which provide all these things. However, we had to prioritize our efforts with the available resources in mind. As a result we found ways and means to tweak Java as good as possible to allow for relatively convenient, high performing implementations.

Java is fast and can easily be debugged but ranks behind Xtend regarding convenience. We address this with different approaches to make Java development in the context of Xtext as comfortable as possible.

Most of the APIs in TMF Xtext use polymorphic dispatching, which mimics the behavior known from Xtend. Another valuable feature of Xtend while working with oAW Xtext is static type checking while working with the inferred Ecore model whereas in Java the work with dynamic Ecore classes was rather cumbersome. Since TMF Xtext generates static Ecore classes per default you get static typing in Java

as well. Additionally, the use of [Google Collections](#) reduces the pain when navigating over your model to extract information.

With these techniques an `ILabelProvider` that handles your own `EClasses` `Property` and `Entity` can be written like this:

```
public class DomainModelLabelProvider extends DefaultLabelProvider {

    String label(Entity e) {
        return e.getName();
    }

    String image(Property p) {
        return p.isMultiValue() ? "complexProperty.gif": "simpleProperty.gif";
    }

    String image(Entity e) {
        return "entity.gif";
    }

}
```

As you can see this is very similar to the way one describes labels and icons in oAW Xtext, but has the advantage that it is easier to test and to debug, faster and can be used everywhere an `ILabelProvider` is expected in Eclipse.

6.3.4. Conclusion

Just to get it right, Xtend is a very powerful language and we still use it for its main purpose: code generation and model transformation. The whole generator in TMF Xtext is written in Xpand and Xtend and its performance is at least in our experience sufficient for that use case. Actually we were able to increase the runtime performance of Xpand by about 60% for the Galileo release of M2T Xpand. But still, live execution in the IDE and on typing is very critical and one has to think about every millisecond in this area.

As an alternative to the Java APIs we also considered other JVM languages. We like static typing and think it is especially important when processing typed models (which evolve heavily). That's why Groovy or JRuby were no alternatives. Using Scala would have been a very good match, but we didn't want to require knowledge of Scala so we didn't use it and stuck to Java.

6.4. Differences

In this section differences between oAW Xtext and TMF Xtext are outlined and explained. We'll start from the APIs such as the grammar language and the validation and finish with the different hooks for customizing linking and several UI aspects, such as outline view and content assist. We'll also try to map some of the oAW Xtext concepts to their counterparts in TMF Xtext.

6.4.1. Differences in the grammar language

When looking at a TMF Xtext grammar the first time it looks like one has to provide additional information which was not necessary in oAW Xtext. In oAW Xtext *.txt files started with the first production rule where in TMF Xtext one has to declare the name of the language followed by declaration of one or more used/generated meta models:

TMF Xtext heading information

```
grammar my.namespace.Language with org.eclipse.xtext.common.Terminals
generate myDsl "http://www.namespace.my/2009/MyDSL"

FirstRule : ...
```

In oAW Xtext this information was provided through the generator (actually it is contained in the *.properties file) but we found that these things are very important for a complete description of a

grammar. Therefore we made that information becoming a part of the grammar language in order to have self-describing grammars and allow for sophisticated static analysis, etc..

Apart from the first two lines the grammar languages of both versions are more or less compatible. The syntax for all the different EBNF concepts (alternatives, groups, cardinalities) is similar. Also assignments are syntactically and semantically identical in both versions. However in TMF Xtext some concepts have been generalized and improved:

6.4.1.1. String rules become Datatype rules

The very handy String rules are still present in TMF Xtext but we generalized them so that you don't need to write the 'String' keyword in front of them and at the same time these rules can not only produce EStrings but (as the name suggests) any kind of EDataType. Every parser rule that does neither include assignments nor calls any that does returns an EDataType containing the consumed data. Per default this is an EString but you can now simply create a parser rule returning other EDataType as well (see [TODO-REF](#)).

```
Float returns ecore::EDouble : INT ( '.' INT )?;
```

6.4.1.2. Enum rules

Enum rules have not changed significantly. The keyword has changed to be all lower case ('enum' instead of 'Enum'). Also the right-hand side of the assignment is now optional. That is in oAW Xtext:

```
Enum MyEnum : foo='foo' | bar='bar';
```

becomes

```
enum MyEnum : foo='foo' | bar='bar';
```

and because the name of the literal equals the literal value one can omit the right-hand side in this case and write:

```
enum MyEnum : foo | bar;
```

6.4.1.3. Native rules

Another improvement is that we could replace the blackbox native rules with full-blown EBNF syntax. That is native rules become terminal rules and are no longer written as a string literal containing ANTLR syntax.

Example :

```
Native FOO : "'f' 'o' 'o'";
```

becomes

```
terminal FOO : 'f' 'o' 'o';
```

See the reference documentation for all the different expressions possible in terminal rules ([TODO-REF](#)).

6.4.1.4. No URI terminal rule anymore

We decided to remove the URI terminal. The only reason for the existence was to mark the model somehow so that the framework knows what information to use in order to load referenced models. Instead we decided to solve this similar to how we imply other defaults: by convention.

So instead of using a special token which is syntactically a STRING token, the default import mechanism now looks for EAttributes of type EString with the name 'importURI'. That is if you've used the URI token like this:

```
Import : 'import' myReference=URI;
```

you'll have to rewrite it that way

```
Import : 'import' importURI=STRING;
```

Although this changes your meta model, one usually never used this reference explicitly as it was only there to be used by the default import mechanism. So we assume and hope that changing the reference is not a big deal for you.

6.4.1.5. Return types

The syntax to explicitly declare the return type of a rule has changed. In oAW Xtext (where this was marked as 'experimental') the syntax was:

```
MyRule [MyType] : foo=ID;
```

in TMF Xtext we have a keyword for this :

```
MyRule returns MyType : foo=ID;
```

This is a bit more verbose, but at the same time more readable. And as you don't have to write the return type in most situations, it's good to have a more explicit, readable syntax.

6.4.2. Differences in Validation

TMF Xtext still supports implementing validation using Xpand's Check. However it is no longer using the EMF meta model (typesystem) but now uses the so called JavaBeansMetamodel. This means that the types in Check and Xtend correspond to Java types. This requires minor changes (namely the namespaces to be imported are now the qualified name of the generated Java classes). Example: If your Check file looked like this in oAW Xtext :

```
import myMetamodel;
context Type ERROR "foo" : name!=null;
```

it becomes something like the following in TMF Xtext :

```
import my::pack::to::myMetaModel;
context Type ERROR "foo" : name!=null;
```

Where `my::pack::to::myMetaModel` refers to the package the generated EClasses are in. In other words there's a Java class `my.pack.to.myMetaModel.Type`. We changed this in order to allow use of any Java API from within Check and Xtend.

6.4.3. Differences in Linking

The linking has been completely redesigned. In oAW Xtext linking was done in a very naive way: To find an element one queries a list of all 'visible' EObjects, then filters out what is not needed and tries to find a match by comparing the text written for the crosslink with the value returned by the `id()` extension. As a side-effect of `link_feature()` the reference is set.

The code about selecting and filtering `allElements()` usually has been duplicated in the corresponding content assist function, so that linking and content assist are semantically in sync. If you're good (we usually were not) you externalized that piece of code and reused the same extension in content assist and linking.

To put it bluntly this approach could be summarized in two steps:

1. Give me the whole universe including every unregarded object in the uncharted backwaters of the unfashionable end of the western spiral arm of the galaxy and squeeze it into an ArrayList
2. From this, select the one I need

This was not only very expensive but also lacks an important abstraction: the notion of scopes.

6.4.3.1. The idea of scopes

In TMF Xtext we've introduced scopes and scope providers that are responsible for creating scopes. A scope is basically a set of name->value pairs. Scopes are implemented upon Iterables and are nested to

build a hierarchy. With scopes we declare “visible” objects in a lazy and cost-saving way where the linker only navigates as far as necessary to find matching objects. The content assist reuses this set of visible objects to offer only reachable objects.

When the linking has to be customized scoping is where most of the semantics typically goes into. By implementing an [IScopeProvider](#) for your language linking and content assist will automatically be kept in sync since both use the scope provider.

The provided default implementation is semantically mostly identical to how the default linking worked in oAW Xtext:

1. Elements which have an attribute ‘name’ will be made visible by their name
2. Referenced resources will be put on the (outer) scope by using the ‘importURI’- naming convention and will only be loaded if necessary
3. The available elements are filtered by the expected type (i.e. the type of the reference to be linked)

6.4.3.2. Migration

We expect the migration of linking to be very simple if you’ve not changed the default semantics that much. We’ve already migrated a couple of projects and it wasn’t too hard to do so. If you have changed linking (and also content assist) a lot, you’ll have to translate the semantics to the [IScopeProvider](#) concept. This might be a bit of work, but it is worth the effort as this will clean up your code base and better separate concerns.

6.4.4. Differences in UI customizing

In oAW Xtext several UI services such as content assist, outline view or the label provider have been customized using Xtend. In TMF Xtext there is no Xtend API for these aspects. Extensive model computations for the content assist is most probably not necessary anymore- it reuses scopes. And since we provide a declarative Java API that mimics the polymorphic dispatch and relies on static `Ecore` classes you will gain nearly the same expressiveness as before while increasing maintainability and performance.

Beside the API change in favor of Java we have to mention that in TMF Xtext the outline view does not support multiple view points so far. This is just because we didn’t manage to get this included. We don’t think that view points are a bad idea in general, but we decided that other things were more important.

6.5. New Features

This section provides an overview of new possibilities with TMF Xtext compared to oAW Xtext. Please note that this list is neither complete nor does it explain every aspect in detail to keep this document tight.

6.5.1. Dependency Injection with Google Guice

Beyond the mentioned architectural overhaul that carve out separate concerns in a meaningful way these different classes of TMF Xtext are wired using [Google Guice](#) and can easily be replaced by or combined with your own implementation. We could have foreseen some common needs for adaption but with this mechanism you can virtually change every aspect of Xtext without duplicating an unmanageable amount of code.

6.5.2. Improvements on Grammar Level

The Xtext grammar language introduces some new features, too. Read the chapter [grammar language](#) to understand the details about all the improvements that have been implemented.

[Grammar mixins](#) allow you to extend existing languages and change their concrete and abstract syntax. However the abstract syntax (i.e. the `Ecore` model) can only be extended. This allows you to reuse existing validations, code generators, interpreters or other code which has been written against those types.

In oAW Xtext common terminals like `ID`, `INT`, `STRING`, `ML_COMMENT`, `SL_COMMENT` and `WS` (whitespace) were hard coded into the grammar language and couldn’t be removed and hardly overridden. In TMF Xtext these terminals are imported through the newly introduced grammar mixin mechanism from the shipped `org.eclipse.xtext.common.Terminals` per default. This means that they are still there but reside in a libraries now. You don’t have to use them and you can come up with your own set of reusable rules.

[Reusing existing Ecore models](#) in oAW Xtext didn't work well and we communicated this by flagging this feature as 'experimental'. In TMF Xtext importing existing Ecore models is fully supported. Moreover, it is possible to import a couple of different EPackages and generate some at the same time, so that the generated Ecore models extend or refer to the existing Ecore models.

The grammar language gained one new concept that is of great value when writing left-factored grammars (e.g. expressions). With actions one can do minor AST rewritings within a rule to overcome degenerated ASTs. You will find an [in-depth explanation of actions](#) in the dedicated chapter in the reference documentation.

6.5.3. Fine-grained control for validation

In order to make more expensive validations possible without slowing down the editor, TMF Xtext supports three different validation hooks.

1. FAST constraints are triggered by the reconciler (i.e. 500 ms after the last keystroke) and on save.
2. NORMAL constraints are executed on save only.
3. EXPENSIVE constraints are executed through an action which is available through the context menu.

Please note that when using Xtext models for code generation the checks of all three categories will be performed.

Beside this it is now possible to add information about the feature which is validated.

```
context Entity#name ERROR "Name should start with a capital "+this.name+"." :  
    this.name.toFirstUpper() == this.name;
```

If you add the name of a feature prepended by a hash ('#') in Check, the editor will only mark the value of the feature (name), not the whole object (Entity). Both concepts, control over validation time as well as pointing to a specific feature, complement one another in Check and Java based validation.

6.6. Migration Support

In this document we tried to explain why we decided to change some aspects of Xtext's architecture. We consider most changes as minor but when it comes to scopes you will face a conceptual enhancement that did not exist in oAW Xtext. We tried to explain why it is not easily possible to come up with an adapter for scoping.

That said you might not have the time to do the migration and wished to have advice for migrating, especially from oAW linking to TMF linking. You're welcome to ask any questions in the newsgroup and we'll try to help you as much as possible in order to get your projects migrated. Also, if you don't want to do the migration yourself we (itemis AG) can do the work for you or help you with that.

Chapter 7. The Antlr IP issue (or which parser to use?)

In order to be able to parse models written in your language, Xtext needs to provide a special parser for it. The parser is generated from the language grammar.

Currently it is recommended to use the [Antlr-based](#) parser. Antlr is a very sophisticated parser generator framework based on a so called LL(*) algorithm. It is fast, simple and at the same time has some very nice and sophisticated features. Especially its support for error recovery is much better than what other parser generators provide.

Antlr comes in two parts: the runtime and the generator. Both are shipped under the BSD license and have a clean intellectual property history. However the generator is still implemented in an older version of Antlr (v 2.x), where it was not possible for the Eclipse Foundation to be sure where exactly every line of code originally comes from. Therefore Antlr v 2.x didn't get the needed approval. Eclipse has a strict IP policy, which makes sure that everything provided by Eclipse can be consumed under the terms of the Eclipse Public Licence. The details are described in [this document](#).

Unfortunately as the generator of Antlr V3 needs Antlr V2 it is as well not yet IP approved. That is why we are not allowed to ship Xtext with the Antlr generator (the runtime is IP approved), but have to provide it separately via updatesite at:

* <http://download.itemis.com/updates/milestones>

IMPORTANT *Although If you use the non-IP approved Antlr generator, you can still ship any languages and the IDEs you've developed with Xtext without any worrying, because the **Antlr runtime is IP approved***

7.1. What if I don't want to use non IP-approved code

If you, against all recommendations, need to stick to a fully IP approved generator, you can use the parser generator we've developed. But be warned, although it's fully functional and equally fast, it does not have any error recovery. This makes the editing experience in the editor more or less unacceptable.
